THE ANSWER

by Rudyard Kipling

A Rose, in tatters on the garden path,
Cried out to God and murmured 'gainst His Wrath,
Because a sudden wind at twilight's hush
Had snapped her stem alone of all the bush.
And God, Who hears both sun-dried dust and sun,
Had pity, whispering to that luckless one,
"Sister, in that thou sayest We did not well --
What voices heardst thou when thy petals fell?"
And the Rose answered, "In that evil hour
A voice said, `Father, wherefore falls the flower?
For lo, the very gossamers are still.'
And a voice answered, `Son, by Allah's will!'"

Then softly as a rain-mist on the sward,
Came to the Rose the Answer of the Lord:
"Sister, before We smote the dark in twain,
Ere yet the stars saw one another plain,
Time, Tide, and Space, We bound unto the task
That thou shouldst fall, and such an one should ask."
Whereat the withered flower, all content,
Died as they die whose days are innocent;
While he who questioned why the flower fell
Caught hold of God and saved his soul from Hell.

Rudyard Kipling (**1809-1849**) ♠

♠ **Joseph Rudyard Kipling** (30 December 1865 – 18 January 1936) was an English short-story writer, poet, and novelist. He is chiefly remembered for his tales and poems of British soldiers in India and his tales for children. He was born in Bombay, in the Bombay Presidency of British India, and was taken by his family to England when he was five years old. Kipling is best known for his works of fiction, including The Jungle Book (a collection of stories, which includes and his poems, including "Mandalay" (1890), "Gunga Din" (1890), "The Gods of the Copybook Headings" (1919), "The White Man's Burden" (1899), and "If—" (1910). He is regarded as a major "innovator in the art of the short story"; his children's books are enduring classics of children's literature; and his best works are said to exhibit "a versatile and luminous narrative gift".

Modelling and simulation for the network-locomotive coupling of the co-phase continuous power supply and high speed railway

School of Electric Power Engineering, Kunming University of Science and Technology, Kunming 650500, China

Received 1 October 2014, www.cmnt.lv

Abstract

Co-phase continuous power supply system (CCPSS) can completely eliminate electric phase break to realize the co-phase continuous power supply in the traction substation, thus the impact on the power quality of the utility grid can be greatly reduced. In this paper, double-loop control strategy, which involves the load current feedback for three-phase pulse width modification (PWM) rectifier and single-phase inverter in the traction substation were proposed. Also, the control strategy with neutral-point-potential balance for three-level rectifier as well as the constant V/f control for asynchronous motor of electric locomotive was proposed. A network-locomotive coupling model of an AC-DC-AC traction substation and electric locomotive was built in this paper using PSCAD/EMTDC. Thorough simulations were conducted to demonstrate the effectiveness of the proposed control strategies.

Keywords: CCPSS, AC-DC-AC electric locomotive of CRH2, control strategy, PSCAD/EMTDC

1 Introduction

In order to reduce the impact of traction power supply system on utility grid imbalance, the traction substation needs to be connected to the utility grid in turns; therefore an electric phase break section should be set at the output interface of a traction substation. Because of the existing of the electric phase break, the locomotive speed and traction power supply capacity were restricted seriously. To solve these technical problems, literature [1-3] put forward the scheme of co-phase power supply which based on active power filter and different connection forms of transformer. The method balanced the transform from three-phase AC to single-phase AC, and could compensate the harmonics and reactive power. However, these schemes could not realize the inter-connection of the power grid in a traction substation. Thus, it cannot cancel the electric phase break completely.

Literature [4-11] proposed a full transformation structure of the three-phase AC to DC to single-phase AC of the traction substation. In this way, there is no need of the electric phase break, so the electrified railway can be achieved to CCPSS. This structure reduced the impact of traction power supply system on utility grid power quality greatly. At the same time, the electric locomotives can be driven stable and safe high-speed.

In this paper, the network-locomotive coupling model of AC-DC-AC traction substation and electric locomotive was established using PSCAD/EMTDC.

Research the control strategies of traction substations and AC-DC-AC electric locomotives based on PWM.

2 The main structure of CCPSS

Compared with the original traction power supply system, the voltage magnitude, phase and frequency of traction network side of the CCPSS were the same, so the electrical phase break could be abolished completely, and it was suitable for high-speed rail operation. Since the substation used PWM symmetric transformation technology of three-phase rectifier to single inverter [12-16], this method could eliminate the interference between the utility grid and traction power supply system in the power quality. When the circuit breaker of the section post was closed, the substations could reach co-phase continuous power supply. The main structure was showed in Figure 1.

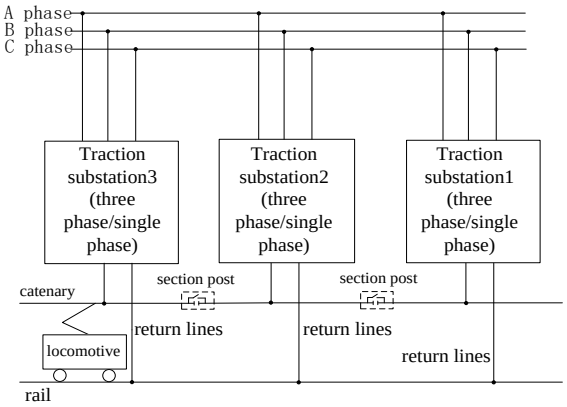

FIGURE 1 The main structure of the CCPSS

*Corresponding author e-mail: chenshilong3@126.com

3 The power converter's main circuit structure of the traction substation

This traction substation was based on the power converter of three-phase PWM rectifier and single-phase PWM inverter. Three-phase PWM rectifier was connected with the step-down transformer. When the DC voltage of rectifier was stable, the unity power factor should be achieved at the same time. Single-phase PWM inverter connected step-up transformer, on the one hand, the output voltage magnitude and frequency were stable; on the other hand, the reactive power, harmonics of the traction load should be compensated real-time. Due to the power supply mode of the traction substations was the AC-DC-AC symmetrical full transformation, traction power supply system and the utility grid were independent, and the three-phase load was balanced, so there was no negative sequence problems.

4 The power converter control strategy of the traction substation

4.1 THE CONTROL STRATEGY OF THE THREE-PHASE PWM RECTIFIER

Since the voltage mode of three-phase PWM rectifier [17] has several advantages, such as: adjustable power factor, low harmonics injected of AC side, DC side voltage stability and to work with the four-quadrant and two-way flow of energy, this control strategy was used in this article.

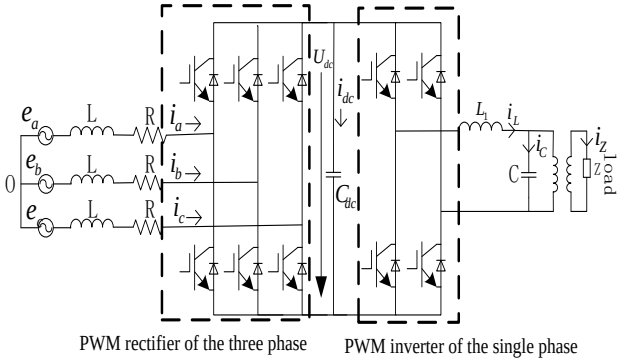

FIGURE 2 The main circuit configuration diagram of the power converter

This control of rectifier mainly included hysteresis current control, predictive current control, resonance control and linear PI controller [18]. Its control method had fast current response and robustness; by comparison, the voltage and current double closed loop PI controller [19] were used in this paper. Meanwhile, in order to improve the anti-jamming capability of rectifier side DC voltage, the paper increased the load current feedback compensation control, so that the power of three-phase PWM rectifier input and output could be balanced, the modulation method using SPWM. Figure 2 shown the equations of three-phase PWM rectifier circuit in ABC coordinates:

$$\begin{cases} C_{dc}\dfrac{du_{dc}}{dt} = i_a S_a + i_b S_b + i_c S_c - i_{dc} \\ L\dfrac{di_a}{dt} + Ri_a = e_a - u_{dc}S_a - u_{NO} \\ L\dfrac{di_b}{dt} + Ri_b = e_b - u_{dc}S_b - u_{NO} \\ L\dfrac{di_c}{dt} + Ri_c = e_c - u_{dc}S_c - u_{NO} \\ u_{NO} = -\dfrac{1}{3}u_{dc}(S_a + S_b + S_c) \end{cases} . \quad (1)$$

(S_a, S_b, S_c - Continuity and shutdown of the upper and lower bridge arm, u_{dc} - the rectifier side DC voltage i_a, i_b, i_c, e_a, e_b, e_c - the current and voltage of AC side; u_{NO} - the neutral point voltage). Through the stationary coordinate ABC to dq0 rotating coordinate transform, the equation of three-phase PWM rectifier under dq0 coordinates could be achieved as follows:

$$\begin{cases} L\dfrac{di_d}{dt} + Ri_d = e_d - U_{dc}S_d + \omega L i_q \\ L\dfrac{di_q}{dt} + Ri_q = e_q - U_{dc}S_q - \omega L i_d \\ C_{dc}\dfrac{du_{dc}}{dt} = \dfrac{3}{2}\left(i_d S_d + i_q S_q\right) - i_{dc} \end{cases} . \quad (2)$$

Let $U_d = U_{dc}S_d, U_q = U_{dc}S_q$, the following equation:

$$\begin{cases} U_d = e_d - L\dfrac{di_d}{dt} - Ri_d + \omega L i_q \\ U_q = e_q - L\dfrac{di_q}{dt} - Ri_q - \omega L i_d \end{cases} \quad (3)$$

In the Equations (2) and (3), i_d, i_q, e_d, e_q, respectively represented the current and voltage under the dq0 coordinate; where ω was the Angular frequency; S_d, S_q respectively represented continuity and shutdown function under the dq0 coordinate. i_{dc} isyhe rectifier side current.

The Equations (2) and (3) show that, when the current i_{dc} changed, the u_{dc} deviated firstly, then the system was adjusted, because the PI regulator delayed, the adjustment process of DC voltage u_{dc} resulted in large errors. In order to strengthen the stability of the DC voltage of three-phase PWM rectifier, a load current feedback compensation link was added. If we ignored line losses and switching losses, the Equation was:

$$\frac{3}{2}\left(e_d i_d + e_q i_q\right) = U_{dc}\left(C_{dc}\frac{du_{dc}}{dt} + i_{dc}\right), \quad (4)$$

when the system was stable, $i_q = 0$, $C_{dc}\dfrac{d_{uc}}{dt} = 0$ the equation was:

$$\frac{3}{2}e_d i_d = U_{dc} i_{dc}. \tag{5}$$

Because of the PI regulator, the current loop without static error tracking could be achieved, if we ignored the adjustment process of the current loop, front feed control variables of the load current was:

$$i_d^* = \frac{2}{3} \times \frac{U_{dc}}{e_d} \times i_{dc}. \tag{6}$$

Figure 3 showed the three-phase PWM rectifier joined the double-loop control system of the load current feedback loop:

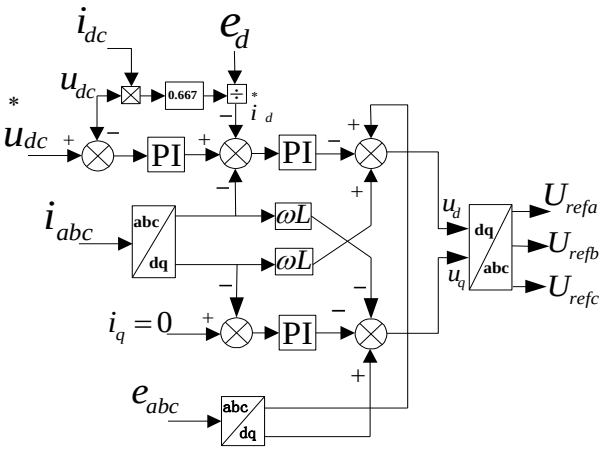

FIGURE 3 Joined the load current feedback loop of the double-loop control system

Double-loop PI control of three-phase PWM rectifier generated three-phase voltage as the reference signal was compared with the triangular carrier, and each switch action pulses to drive each switch-off and switch-on were got.

4.2 THE CONTROL STRATEGY OF SINGLE-PHASE PWM INVERTER

Because the double-loop controller had several characteristics [20, 21], such as: design simple, the output voltage waveform distortion small, fast dynamic response, and it required the power converter accurate tracking given traction load current, this control method was used in this article for the control of single-phase PWM inverter. The control system was shown in Figure 4.

The mathematical model of single-phase PWM inverter circuit was:

$$\begin{pmatrix} L_1 \dfrac{di_L}{dt} \\ L_1 \dfrac{du_c}{dt} \end{pmatrix} = \begin{pmatrix} u_{dc} \\ i_L \end{pmatrix} - \begin{pmatrix} u_C \\ i_Z \end{pmatrix}, \tag{7}$$

where i_L was the current of filter inductor; u_{dc} was the voltage of filter capacitor; i_z was the load current.

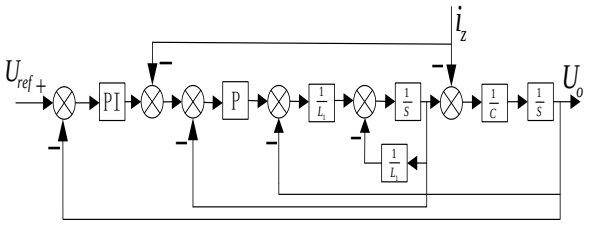

FIGURE 4 Single phase inverter control block

5 The converter main circuit structure of the AC-DC-AC electric locomotive traction

Currently, there are mainly two types of the traction converters，the one is the AC-AC converter, the other one is the AC-DC-AC converter.

The AC traction drive system generally adopted the following basic structure of AC-DC-AC electric locomotive:

The traction supply system of asynchronous motor power supply used voltage type AC-DC-AC converter; the traction supply system of synchronous motor power supply used current type AC-DC-AC converter, the traction supply system of synchronous motor power supply used AC-AC converter [22].

Compared with current type converter, the output current waveform of the voltage type converter contained less harmonic components [23]. Its performance was superior, the current waveform were closer sine. In summary, this paper adopted voltage type AC-DC-AC converter as the electric locomotive traction converters [24]. The main circuit configuration was shown in Figure 5.

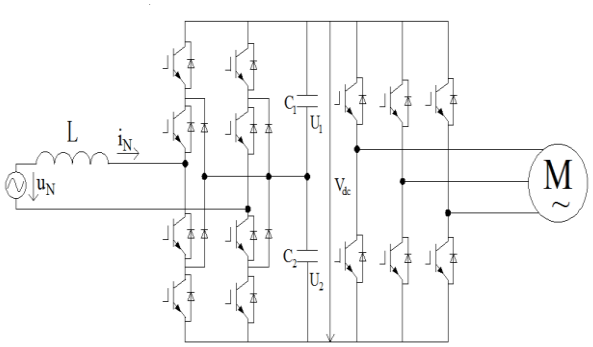

FIGURE 5 Traction converter main circuit diagram

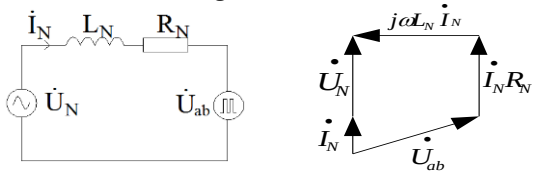
The traction substation of decreasing from single-phase AC 27.5KV to 1.5KV single-phase AC; through three-level PWM rectifier to 2.6kV~3kV DC for the three-phase PWM inverter, three-phase PWM inverter and motor control as a whole, using the control mode of VVVF (variable voltage variable frequency).

5.1 THE CONTROL STRATEGY OF TRACTION CONVERTER

5.1.1 The control strategy of the single phase three-level PWM rectifier

Analysing rectifier side of Figure 5，the equivalent circuit diagram of the AC side of the rectifier and its control vector were shown in Figure 6.



a) Equivalent circuit diagram b) Control vector

FIGURE 6 Equivalent circuit and control vector of rectifier

In the Figure 6, where $\dot{U}_N$ was the voltage of the secondary winding of vehicle transformer, R_N , L_N ,were converted to resistance and leakage inductance of secondary side of the transformer windings respectively; $\dot{U}_{ab}$ was the fundamental vector of modulation voltage. Figure 6b showed the voltage vector equation of vehicle transformer secondary AC circuit:

$$\dot{U}_N = \dot{U}_{ab} + (R_N + j\omega L_N)\dot{I}_N . \tag{8}$$

The literature [25, 26] proposed an improved balance control with a midpoint voltage of transient current control method was used in the rectifier of the CRH2 locomotive. On the basis of Equation (8), when the compensated was increased the control Equation as follows:

$$\overset{*}{I}_{N1} = K_P(\overset{*}{U}_{dc} - U_{dc}) + \frac{1}{T_i}\int(\overset{*}{U}_{dc} - U_{dc})dt , \tag{9}$$

$$\overset{*}{I}_{N2} = \frac{I_{dc}U_{dc}}{U_N} , \tag{10}$$

$$\overset{*}{I}_N = \overset{*}{I}_{N1} + \overset{*}{I}_{N2} , \tag{11}$$

$$\overset{*}{U}_{ab}(t) = u_N(t) - (\overset{*}{I}_N R_N \sin\omega t + \overset{*}{I}_N \omega L_N \cos\omega t) - K[\overset{*}{I}_N \sin\omega t - i_N(t)] . \tag{12}$$

K_p, T_i were the proportional integral constant of PI regulator; K was the constant of PI regulator, i_N was the input current of AC side, other variables could be seen from Figure 7.

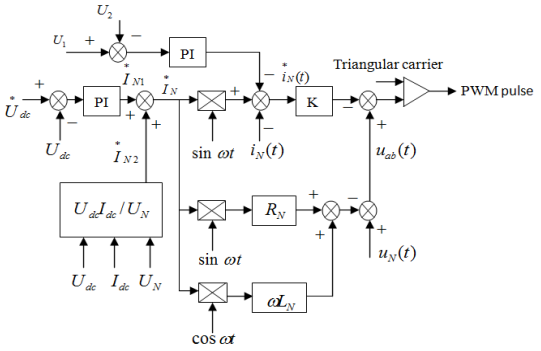


FIGURE 7 The control system block diagram of rectifier

The AC side current for a given value:

$$\overset{*}{i}_N(t) = \overset{*}{I}_N \sin\omega t - [K_{p1}(u_1 - u_2) + \frac{1}{T_{i1}}\int(u_1 - u_2)dt] - i_N(t) . \tag{13}$$

The traction converter rectifier control system block diagram was shown in Figure7.

5.1.2 The control strategies of the three-phase PWM inverter and motor

According to the knowledge about motor, electromagnetic torque *M* and *U/f* had a positive correlation.If the frequency *f* was adjusted, the voltage *U* should also be adjusted. So that the ratio $(U/f)^2$ could remained constant, and the flux ϕ remained unchanged, as well as the value of the torque *M* [27]. Control block diagram was shown in Figure 8.

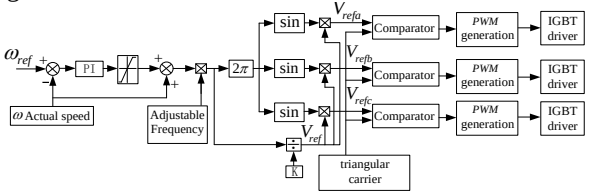

FIGURE 8 The control block diagram of the VVVF motor speed

6 Simulation results and analysis

Based on the PSCAD/EMTDC, the network-locomotive coupling model of AC-DC-AC traction substation and electric locomotive was established.

The main parameters were shown in Table 1.The other parameters of CRH2 according to the literature [28].

TABLE 1 The main parameters of the model

Three-phase power system	Three-phase rectifier side	Single-phase inverter side	Electric locomotive rectifier side
Fundamental frequency $f = 50Hz$	DC voltage set point $U_{dc} = 5KV$	Filter inductance $L_1 = 0.25mH$	Filter capacitance $C_1 = C_2 = 2200uF$
Source voltage $V_S = 110KV$	DC capacitor capacitance $C_{dc} = 9000uF$	filter capacitance $C = 130uF$	DC voltage set point $V_{dc} = 3KV$
three-phase step-down transformer ratio $110KV/3.5KV$	triangular carrier frequency $f_C = 1000Hz$	triangular carrier frequency $f_{C1} = 1200Hz$	triangular carrier frequency $f_{C2} = 1000Hz$

In this study, the pole-placement method was utilised [20], adjustment them through a lot of simulation experiments, to achieve the desired requirements.
The simulation results were as follows:

1) In this model, the co-phase continuous power supply system consisted of three traction substation, and three traction substations acquire power in the same utility grid together.

2) Traction substation output interface and rectifier of the waveform was shown in Figure 9 to Figure 13.

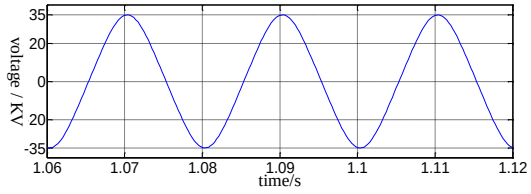

FIGURE 9 The voltage of traction substation 1

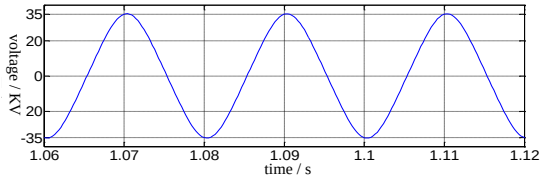

FIGURE 10 The voltage of traction substation 2

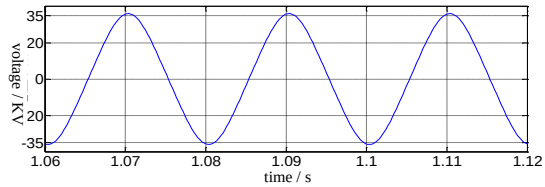

FIGURE 11 The voltage of traction substation 3

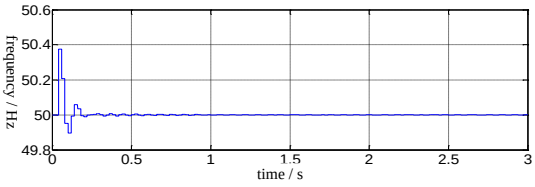

FIGURE 12 The frequency of traction substation

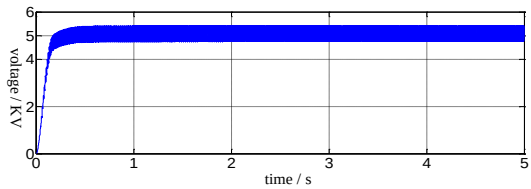

FIGURE 13 The DC voltage of traction substation rectifier side

It could be seen from Figure 9 to Figure 13 that in the case of electric locomotive load conditions, the voltage of traction substation rectifier side and the voltage of the output interface, frequency were stabilized at predetermined 5kV, 27.5kV, 50Hz,and harmonics injected and negative sequence were very low, have a high quality of voltage.

The rectifier side voltage of AC-DC-AC electric locomotive, current of the stator side and the stator flux trajectory waveform were shown in Figures 14-16.

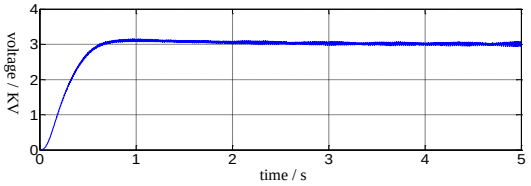

FIGURE 14 the voltage of electric locomotive rectifier side

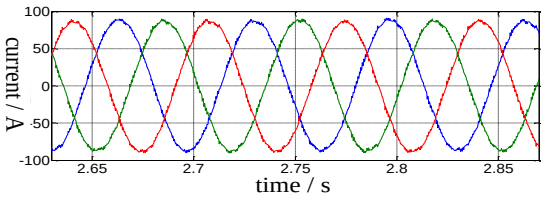

FIGURE 15 The current of the stator side

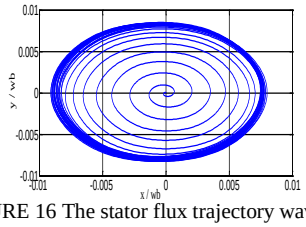

FIGURE 16 The stator flux trajectory waveform

It could be seen from Figure 14 to Figure 16 that, the voltage of electric locomotive rectifier side was stabilized at predetermined 3KV; the three-phase current of the stator side was symmetry. The stator flux trajectory waveform was approximate round.

7 Conclusions

This paper mainly studies the main circuit structure and control strategy of traction substation and AC-DC-AC electric locomotive. Application of electromagnetic transient simulation software PSCAD/EMTDC, it established the network-locomotive coupling model of AC-DC-AC traction substation and electric locomotive.

Through the analysis of this paper and the simulation results, the conclusions were as follows:

1) The voltage magnitude, phase and frequency were the same of three traction substation output interface. The electric phase break is completely cancelled, so the traction substation between the CCPSS is achieved. It reduces the impact of traction substation on the utility grid power quality greatly.

2) The double-loop control strategy of the loaded was suitable, not only the anti-interference ability be improved of DC voltage of three-phase PWM rectifier, but also make the DC voltage to track the command voltage fast.

Research on aircraft burst fault diagnosis based on T-S fuzzy neural network

Hui Yang, Lijing Wang*, Zheng Deng

College of Computer Science and Technology, Civil Aviation University of China, No. 2898 JINBEI Road, Dongli District, Tianjin, China

Received 1 October, www.cmnt.lv

Abstract

Aircraft burst fault is uncertainty and ambiguity. Considering QAR data as the research object, the fault diagnosis system based on the T-S fuzzy neural network combined with aircraft maintenance processes is built. First, the system designs the network performance oversight function to improve genetic neural network program. Then the fuzzy logic is used to deal with fuzzy rules, which can determine the location and severity of fault. And the result proves that the system has strong ability to deal with the questions.

Keywords: aircraft burst fault, QAR data, fuzzy rules, genetic neural network algorithm, T-S fuzzy neural network

1 Introduction

QAR is used for recording flight parameters and working conditions of the various components of airborne equipment [1]. It is streaming data acquired from the sensor, and its sampling frequency is once every second. QAR record details of the true state about aircraft in flight, and the data provide a strong basis to the real-time status monitoring and fault diagnosis of the aircraft.

U.S. National Aeronautics and Space Administration (NASA) have developed APMS (Aviation Performance Measuring System) software to build a model to identify abnormal QAR data, which can found the problems in the mass flight data [2]. UK CAA research centre devote to the Insight FDM system for airlines flight data analysis [3]. However, QAR data are only invoked when the faults happen and need to be removed, resulting in the gradual deterioration of some minor malfunction and causing serious consequences.

This paper uses T-S fuzzy neural network for fault diagnosis, then processes the QAR data modularly according to the structure characteristics of T-S fuzzy neural network system. Firstly, the BP neural network is improved to solve its existing problems for processing data, then making use of the expert experience and knowledge to turn the expert's experience into fuzzy logic rules, and adding fuzzy logic system to the improved BP neural network. Due to the excessive number of the input fuzzy rules, which caused by the size of input attribute values, the parallel network structure is raised in the fault diagnosis of T-S fuzzy neural network. Thus, faults could be detected and repaired according to the discrimination of fault types and assessment of failure severity detected by the output data.

2 The structure of fault diagnosis system

2.1 RELATED PROPERTIES

QAR data has the following characteristics: the sampling frequency is once per second, and the amount of data is very large; meanwhile, the QAR data is strictly in accordance with time, so the relationship between data is strong; besides, the QAR data has many uncertain factors such as some interference. QAR records lots of attribute values, but only parts have close relationship when particular fault occurs.

Related properties of air turbulence and air parking are analysed according to attribute reduction method based on rough set [4] and the maintenance experience provided by airlines, and eight related attributes are statistical: EPR (engine pressure ratio), ALV (vertical acceleration), N1 (low pressure rotor speed), N2 (high pressure rotor speed), EGT (exhaust gas temperature), TAT (total temperature probe signal), V1 (N1 vibration) and V2 (N2 vibration).

2.2 SYSTEM STRUCTURE

Neural network has the advantages of parallel computing, the ability of self-learning and nonlinear mapping ability. The complex relationship between a given input to the desired output can be realized through the network. It has been widely used in processing time series data such as fund price predicting [5], stock trend prediction [6] and so on. But the neural network is not suitable to process expert knowledge based on rules, while ignoring the system of expert experience knowledge often have a lot of defects in engineering; and fuzzy logic is suitable for processing some fuzzy or uncertain knowledge, but it does not have the ability of adaptive learning [7].

Aircraft quick access recorder (QAR) stores complex and a large number of data. Simply using the BP neural network to detect the abnormal data presents some problems, such as network convergence instability, slow and low accuracy. Therefore, on the basis of BP neural network, we propose an improved genetic neural network. Because of the defect of improved neural network model in lacking of using the expertise knowledge to handle aircraft emergencies troubleshooting process, we introduce the T-S fuzzy neural network exploration to research aircraft fault diagnosis. Figure 1 shows the whole procedures.

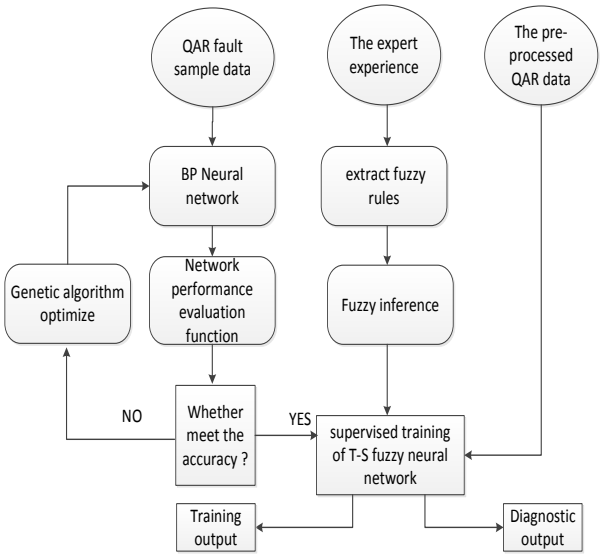

FIGURE 1 Fault diagnosis flow chart of T-S fuzzy neural network

3 Improved BP neural network algorithm

Back Propagation neural network is nonlinear mapping, parallel computing and self-learning [8]. However, simply using BP neural network to process fault QAR data has many problems such as the poor stability of convergence and low speed. As global search optimization algorithms, Genetic Algorithms is always used to improve BP neural network [9]. According to the characteristics of QAR data, we design a function to evaluate network convergence performance.

The network training times are divided into some parts with the same number, then calculating and recording the average error of each section, comparing the current average error with the last average error and the error setting before. If the current is greater than the set and less than the last, it shows that the internet has not yet reached saturation, continue training; if the current is greater than the set and equal to the last, it indicates that the network has been plunged into saturation, and genetic algorithms should be introduced. Terminate network training, extract weights and thresholds in BP neural network and encode as chromosome, which is used to form population with randomly generated chromosomes for genetic operation. The improved genetic neural network flow chart is shown in Figure 2.

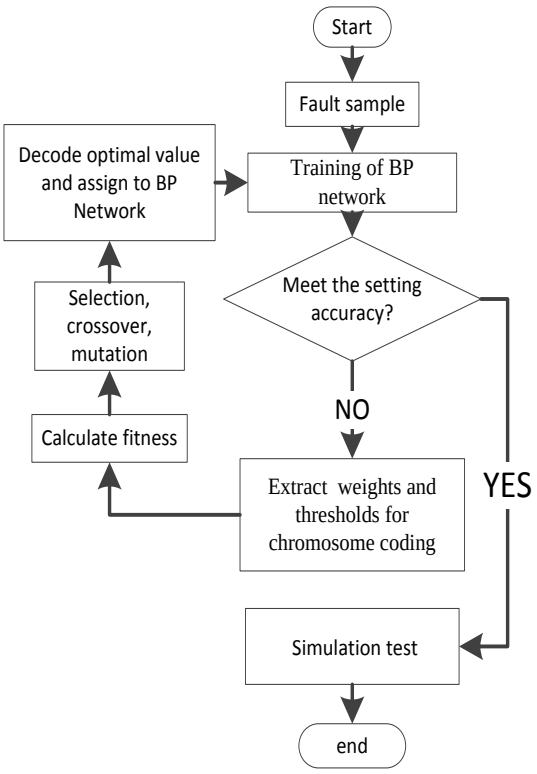

FIGURE 2 The process of improved genetic neural network

Based on the flow chart of improved genetic neural network, the steps of the algorithm can be designed for the diagnosis of QAR abnormal data.

1) Enter the eight values of air turbulence and air parking $X=\{x_1,x_2,\cdots x_8\}$, named EPR, ALV, N1, N2, TAT, EGT, V1 and V2, and the two kinds of output fault types are air turbulence and air parking. The appropriate number of neurons in the hidden layer based on empirical values and experiment is eight.

2) The input feature value is passed to the hidden layer neurons through the input layer neurons, and the transfer function is S-shaped function:

$$f(x)=1/1+e^{-ax}, \tag{1}$$

where a is the slope factor of S-function which can be adjusted freely. After calculation of hidden layer neurons function, we can get the output:

$$H_j=f\left(\sum_{i=1}^{8}\sum_{j=1}^{8}w_{ji}*X+\theta_j\right), \tag{2}$$

where w_{ji} is random initialization weights matrix between input layer and hidden layer; θ_j is random initialization threshold matrix of hidden layer neurons function, and the linear transfer function of output layer is:

$$\phi(x)=ax+b. \tag{3}$$

And the final output is:

$$O_k = \phi\left(\sum_{j=1}^{8}\sum_{k=1}^{2} \upsilon_{kj} * H_j + \theta_k\right), \tag{4}$$

where υ_{kj} is the random initialization weights matrix between hidden layer and output layer; θ_k is random initialization threshold matrix of output layer, and the total error is:

$$E = \frac{1}{2}\sum_{s=1}^{S}\left(O_s - T_s\right)^2, \tag{5}$$

where E is the sum of squared errors between the supervise values and the actual output value after sample data is trained, S is total number of the sample data, and the error back propagation algorithm named train is used.

3) Determine whether to use genetic algorithm to optimize BP neural network by the network performance evaluation function. Set the training times to n, $[1,n]$ represents the interval of training times, the value of n is set based on the sample size combined with the experiment, while the principle is to make the network speed as fast as possible. Training times will be divided as the same interval, and the quantity is $k = L/n$. $\overline{E}$ is the mean square error for each interval training of network, so

$$\overline{E} = E_1 + E_2 + \cdots + E_n / n. \tag{6}$$

Within such a range of k, we can obtain a row vector of error: $\left[\overline{E_1} \quad \overline{E_2} \quad \cdots \quad \overline{E_k}\right]$, for any two elements of the vector $\overline{E}_i$ and $\overline{E}_{i+1}$ $\left(i \in 1,2,\cdots,k\right)$, set $E_{trainerror}$ as error precision of network, if BP neural network training error satisfies the following Equation:

$$\begin{cases} \overline{E}_{i+1} > E_{trainerror} \\ \overline{E}_i > \overline{E}_{i+1} \end{cases}. \tag{7}$$

It means the BP neural network has not reached saturation point, continue training; if BP neural network training process error satisfies the following Equation:

$$\begin{cases} \overline{E}_{i+1} > E_{trainerror} \\ \overline{E}_i = \overline{E}_{i+1} \end{cases}. \tag{8}$$

It means the network reaches saturation and the error does not converge to the range of setting accuracy, then turn into the genetic algorithm optimization.

4) Terminate the train of BP neural network and extract the neural network weights and thresholds matrix when the neural network reached saturation. Do real number code according to the order of weight matrix of input layer to the hidden layer, the threshold matrix of hidden layer, weight matrix of hidden layer to the output layer and the threshold matrix of output layer, and the code can be expressed as

$$chrom = (w_{ji}\ \theta_j\ v_{kj}\ \theta_k). \tag{9}$$

Randomly generate the rest of the chromosomes to form the initial population.

5) Each chromosome is decoded as the BP neural network weights and thresholds, and the actual output of the network can be drawn from the sample data entered. The corresponding chromosome fitness is the reciprocal value of the sum of squares of the error between the actual output and the supervising:

$$f(i) = 1\Big/\frac{1}{2}\sum_{s=1}^{S}\left(O_s - T_s\right)^2, \tag{10}$$

where s is the number of samples. Crossover and mutate on population until genetic algorithm optimization process achieve the iteration times. Find out the chromosome with maximum fitness value, and decode the optimal chromosome as weights and thresholds matrix according to the inverse operation of encoding, then assigned the values to BP neural network, turn to steps 2 to continue training;

6) If the network converges, finishing the training, and the network can be used to QAR data detection; if not, turn to step 4).

4 Fuzzy neural network model

T-S model uses the consequent of fuzzy rules as function of the input linguistic variables [10]. In the fuzzy reasoning part of T-S network, fuzzy rules will exponentially grow with the input fuzzy partition number increasing. If fuzzy partition number is too many, it will result in the dimensionality curse of rules [5]. In order to reduce the difficulties, we set two T-S fuzzy neural networks apart for fault types. And the network framework is as follows:

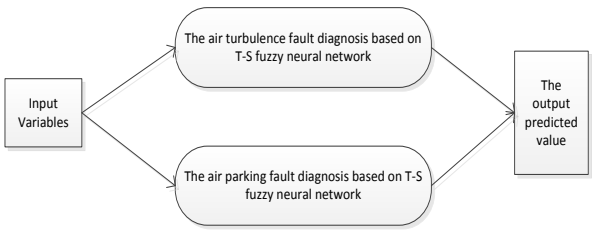

FIGURE 3 The overall design of the T-S network diagnosis system

We set air turbulence T-S fuzzy neural network as example to build network structure. The network structure is shown in Figure 4. Air parking T-S fuzzy neural network can be structured with the same approach of air turbulence, and then constitute a parallel network.

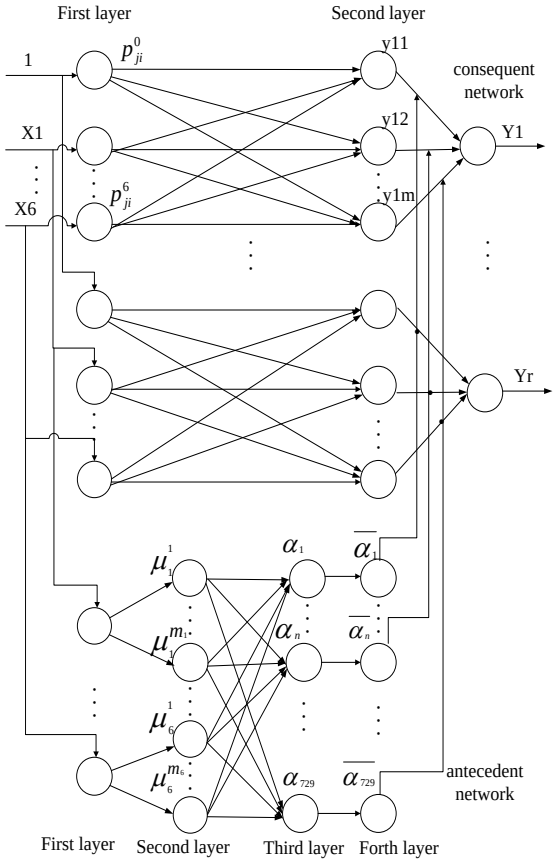

FIGURE 4 T-S network diagnosis structures

4.1 ANTECEDENT NETWORK

Antecedent network consists of four layers. The first layer is the input layer, and the input values $x=[x_1, x_2 \ldots x_6]^T$ represent 6 attribute values associated with air turbulence. The number of nodes in first layer is $N_1 = n$. At the second layer, each node represents a linguistic variable values, such as positive, zero, negative. Its role is to calculate the membership degree of the input component part $\mu_i^{S_i}$, where $\mu_i^{S_i} = \mu_{A_i^{S_i}}(x_i)$ $(i=1,2,\cdots,6; S_i=1,2,3)$. Input dimension number is 6, and fuzzy division number of x_i is 3. Membership function is Bell-shaped represented by Gaussian functions.

$$\mu_i^{S_i} = \exp - \left\{ \frac{\left(x_i - c_{i_{S_i}}\right)^2}{\sigma_{i_{S_i}}^2} \right\}, \tag{11}$$

where C_{iS_i} and σ_{iS_i} denote the centre and the width of the membership function. The number of nodes in second layer is $N_2 = \sum_{i=1}^{n} m_i = 6 \times 3 = 18$. Each node of the third layer represents a fuzzy rule, and its role is to match the antecedent of the fuzzy rules and calculate the applicable of each rules. The value of a_j is

$$a_j = \min\left\{\mu_1^{S_{1j}}, \mu_2^{S_{2j}}, ..., \mu_n^{S_{nj}}\right\} \tag{12}$$

and the necessary value to calculate a_j is

$$\begin{cases} S_{1j} \in \{1,2,...,m_1\} \\ S_{2j} \in \{1,2,...,m_2\} \\ ... \\ S_{nj} \in \{1,2,...,m_n\} \\ j = 1,2,\cdots,m \\ m = \prod_{i=1}^{n} m_i = 3^6 = 729 \end{cases}. \tag{13}$$

The number of nodes in third layer is $N_3 = m = 729$. For the given input, only linguistic variables near it could have greater membership grade, and those far away from it have smaller values. Therefore only some nodes have greater output, which is equal to a local approximation network. The fourth layer has the same number of nodes as the third layer, $N_4 = N_3 = m = 729$. It mainly do normalized operation

$$\overline{\alpha}_j = \alpha_j \Big/ \sum_{i=1}^{m} \alpha, \; j = 1,2,\cdots,729. \tag{14}$$

4.2 CONSEQUENT NETWORK

This part is composed of parallel sub-networks, and the output is calculated through the network.

The first layer of sub-network is the input layer; it transfers the input variables to the second layer. The node No.0 has value $x_0 = 1$, and its role is to provide the constant term for consequent fuzzy rules. The nodes in the second layer represent fuzzy rules, and its role is to calculate consequents for each rule. The Equation is as follows:

$$y_{kj} = p_j^{k_0} + p_j^{k_1} x_1 + \cdots + p_j^{k_n} x_n = \sum_{l=0}^{n} p_j^{k_l} x_l, \tag{15}$$

where $k = 1,2,\cdots,r$; $j = 1,2,\cdots,m$; $x_0 = 1$.The third layer of sub-network is to compute system's overall output:

$$y_k = \sum_{j=1}^{m} \overline{\alpha}_j y_{kj}, \; (k = 1,2,\cdots r), \tag{16}$$

where y_k is the weighted sum of consequent rules, and the weighting coefficients is the connection weights of third layers of the antecedent network.

4.3 ALGORITHMS OF T-S NETWORK

Weights of the consequent network p_{ji}^k $(j=1,2,\cdots,729; i=1,2,\cdots,6; k=1,2,3)$, central value of membership function c_{ij} and width σ_{ij} $(i=1,2,\cdots,729; \; j=1,2,3)$ should be installed if the T-S fuzzy neural network is used, which could make the linear

mapping from input to output complicated. Set the error cost function as follows:

$$E=\frac{1}{2}\sum_{k=1}^{3}\left(y_{dk}-y_k\right)^2, \tag{17}$$

y_{dk} and y_k are expected output value and actual output value. Learning algorithm of p_{ji}^k, c_{ij} and σ_{ij} is as follows:

1) Set weights between nodes in the network p_{ji}^k, central value of membership function c_{ij} and width σ_{ij} randomly.

2) Input the sample data of air turbulence, then train the network according to the following formulas:

$$\frac{\partial E}{\partial p_{jl}^k}=\frac{\partial E}{\partial y_k}\frac{\partial y_k}{\partial y_{kj}}\frac{\partial y_{kj}}{\partial p_{jl}^k}=-\left(y_{dk}-y_k\right)\overline{\alpha_j}x_l. \tag{18}$$

$$p_{jl}^k(t+1)=p_{jl}^k(t)-\beta\frac{\partial E}{\partial p_{jl}^k}=p_{jl}^k(t)+\beta\left(y_{dk}-y_k\right)\overline{\alpha_j}x_l. \tag{19}$$

$$j=1,2,\cdots,m;\ \ l=0,1,\cdots,n;\ \ k=1,2,\cdots,r.$$

$$c_{is_i}(k+1)=c_{is_k}(k)-\beta\frac{\partial E}{\partial c_{is_i}}, \tag{20}$$

$$\sigma_{is_i}(k+1)=\sigma_{is_i}(k)-\beta\frac{\partial E}{\partial \sigma_{is_i}}, \tag{21}$$

$$i=1,2,\cdots,n;\ \ s_i=1,2,\cdots,m^i\ \ ;\beta>0,$$

and β is learning rate. Regulate the values of p_{ji}^k, c_{ij} and σ_{ij} with the formulas above. And set up a network error oversight function (Specific constructor of the function is described in Section 2.2.1). Monitor the error of output value.

3) If the error is reduced continuously in the setting times of training, then go on using the Equations in step 2 to calculate the error convergence. If the error keeps constant or has minor change in the setting times of training, suspend the network training process temporarily and introduce genetic algorithm to find the optimal values of p_{ji}^k, c_{ij} and σ_{ij}, then assign the values to the network node. Turn to step 2 and continue to train. If the error can reach to the setting precision, it means the network has finished training, stop the training process; if not, go to step 2 and continue training.

5 Experiments and analysis

According to maintenance experience and analysis of failure data, we sort out the six properties and the severity of fault associated with the air turbulence in Table 1. The severity of fault can be inferred through the level of air turbulence fault.

This experiment is designed with the MATLAB R2009a system. 800 groups of sample data collected from the B737-800 aircraft are used, while 750 groups are randomly selected as the training samples and the remaining 50 groups are testing samples. The training times is =1000. According to the repeated experiment, when the learning rate is 0.006, the network has the best effect, and the error precision of training is 0.01. Considering the influence of the uncontrollable factors, the simulation output values representing fault classification should be allowed to exist reasonable error, and the error range in this article is as shown in the Table 2.

TABLE 1 Division of property values and fault level

	Normal	Relatively normal	Slight	Relatively heavy	Heavy
Engine pressure ratio	1.45	1.3	1.2	1.1	1
Vertical acceleration (m/s2)	0.95	0.8	0.7	0.6	<0.5
VIB Vibration ()	0.5	0.4	0.3	0.2	<0.1
Low pressure rotor speed (r/s)	120	110	95	80	<65
High pressure rotor speed (r/min)	90	80	65	45	<25
Exhaust temperature (℃)	650	550	450	400	<400
Output value	1	2	3	4	5

TABLE2 The error range of simulation output

	Normal	Relatively normal	Slight	Relatively heavy	Heavy
Simulation output value (x)	0.5<x<1.5	1.5<x<2.5	2.5<x<3.5	3.5<x<4.5	4.5<x<5.5

Air turbulence fault experiment is done according to the given data and T-S fuzzy neural network system. After experiments, we find that when the training times is 33~56, the error can reach the setting precision. Select the data which could reach the precision within 40 times, and draw an error graph as shown below:

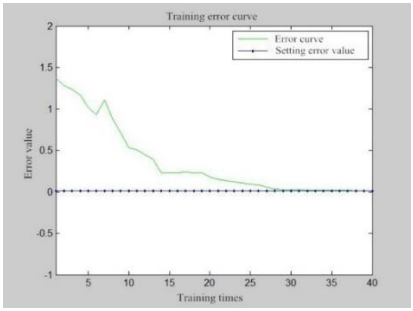

FIGURE 5 Training error curve

The picture is taken from an intermediate value after many training times. As shown in the figure, there is a smooth curve at 15-20 times in the process of training, and the network turns into the genetic algorithm optimization process through the network supervision function, then continue to train after the parameters are optimized until reach the setting error precision value. In order to test the rationality and validity of fault diagnosis system, 50 groups of sample data are used, and the results are as shown below:

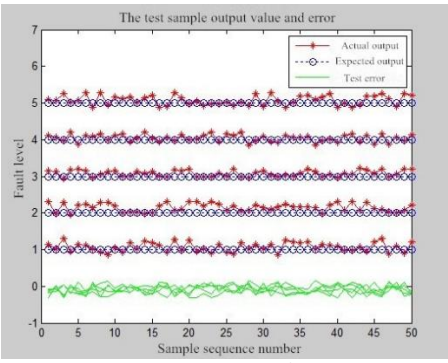

FIGURE 6 The output value of the test sample

As we can see, the result is in the permitted error, and the system can predict fault severity well, which can provide decision support and guidance for the repair. It also reaches our expectation.

6 Conclusions

In this paper, the aircraft faults warning system based on QAR data is realized. The system includes two fault diagnosis subsystems, air turbulence and air parking. Fault models based on QAR data and QAR outlier detection algorithm has been researched and realized. The parallel double network thought has been referred to separate the experimental data and import them to different fault diagnosis sub-system, which greatly simplifies the increasing quantity of fuzzy rules with the input. At the same time, the network training algorithm based on improved genetic algorithm is introduced into the antecedent and consequent parameters in the network training adjustment. The experimental results show that the algorithm has a good effect on sudden fault. It can diagnose the fault type and severity of aircraft effectively.

Because of the complexity of QAR data and information, only two fault types are built, and the fault models combine technical data with expert experience provided from airlines. Whether we need to build more models should be further studied.

Design and implementation of a parallel algorithm based on Hadoop platform

Qingnian Zhang*, Zhao Chen, Zihui Wang

Wuhan University of Technology, China

Received 1 October 2014, www.cmnt.lv

Abstract

Existing clustering algorithm is transplanted into the Hadoop cloud computing platform, through the low price on the computer cluster nodes dynamically allocate huge amounts of data distributed task, solve the enterprise needs a large amount of data storage and the problem of real time analysis results. Graphs programming model can help developers to quickly realize the parallel clustering, and do not need too much to understand the specific underlying communication realization. This article will improve the clustering algorithm, which is transplanted into graphs on the programming model, realize the parallel design, and through the error sum of squares criteria such as function test and verify the reliability of the parallel algorithm. Under the Hadoop cluster composed of four machines respectively samples of different sizes of data clustering analysis, proves that the parallel algorithm of Hadoop platform on the large data applications better speedup and scalability.

Keywords: hadoop platform, mapreduce, clustering, k-mean

1 Introduction

Hadoop open source distributed cloud computing platform by the Hadoop distributed file system and the graphs of programming model. Existing clustering algorithm is transplanted into the Hadoop cloud computing platform, through the low price on the computer cluster nodes dynamically allocate huge amounts of data distributed task, solve the enterprise needs a large amount of data storage and the problem of real time analysis results [1, 2]. Graphs programming model can help developers to quickly realize the parallel clustering, and do not need too much to understand the specific underlying communication realization [3, 4].

Through learning clustering algorithm in data mining, this paper implemented the Hadoop distributed platform parallel Kmeans algorithm, effectively solves the massive user data classification problem.

2 Data clustering application framework design

This system adopts the Hadoop platform Hadoop distributed file system to store user data, with the clustering algorithm into graphs programming for data clustering. Figure 1 is the flow chart for the application of this system framework, which mainly consists of data collection module, data preprocessing module, data storage module and data mining analysis module [5, 6].

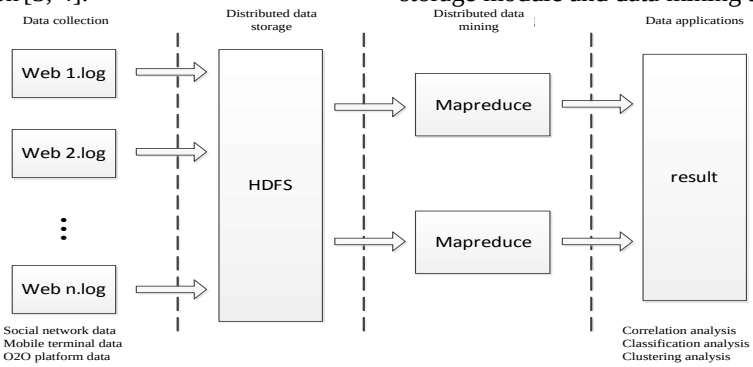

FIGURE 1 System frame

Mapreduce programming model can effectively solve the parallel processing data in the distributed storage and fault tolerance, how could the Hadoop platform to realize the big data mining work, the key is the transfer of the mining algorithm to graphs programming model. Under the framework of the k-means algorithm is transplanted into graphs, the concrete implementation process programming model as shown in Figure 2.

3.1 HARDWARE AND SOFTWARE CONFIGURATION

Website user behaviour data not only are there more big quantity, type, and for real-time analysis of the results, according to the characteristics of this system USES Hadoop platform Hadoop distributed file system to store user data, with transplanted into graphs programming under the clustering algorithm to cluster the user consumption behaviour [7, 8]. By the results of clustering, the difference of customers to provide high quality service, in view of the current marketing activities of the problem, provide favourable data support.

Using 4 PC computer in ubuntu12.04 platform structures, a small cluster with four nodes. Choose one of the highest frequencies of CPU a master, as the main nodes at the same time set up the master and the other three as a slave node. Master node configuration is 1 GB memory size, from the node configuration memory size is 512 m, all 20 GB hard drive size distribution. Every node in the cluster need to install the same version of Hadoop and under the same path JDK version, through a router connection to the machine, every day in the same local area network (LAN). Cluster structures, different from the pseudo distributed mainly in two aspects: the static IP Settings and SSH communications. After launch the Hadoop in a small cluster environment, on the master there should be the JobTracker, SecondaryNameNode, the NameNode, DataNode and TaskTracker five daemons, while slave1, slave2 and slave3 should have DataNode and TaskTracker two daemons. Table 1 below is the Hadoop cluster software and hardware configuration.

TABLE 1 hardware and software configuration information

	master	**slave1**	**slave2**	**slave3**
cpu	2.5GHz	1.79GHz	1.83GHz	1.93GHz
memory	1G	512M	512M	512M
hard disk	20G	20G	20G	20G
operating system		Ubuntu12.04, Windows XP		
open tools		Hadoop-1.0.2, Eclipse, JDK1.6		

3.2 THE HADOOP NODE CONFIGURATION

Hadoop is mainly composed of two basic modules: graphs programming model and Hadoop distributed file system. Graphs programming model is mainly used in distributed applications, this model is a JobTracker and several TaskTracker. After the client send a job application to the JobTracker, JobTracker is responsible for the operations of initialization, job scheduling and monitoring TaskTacker task. As long as find task failure, JobTracker will restart it, guarantee the stability of the cluster. TaskTracker is running on the slave service, responsible for executing the JobTracker distribution of parallel tasks [9, 10]. HDFS distributed file system is used for distributed storage, as the underlying support of graphs, the nodes in the cluster consists of one NameNode and more DataNode. The NameNode's role is to manage the file system namespace, the function of the DataNode is according to the need to store and retrieve data block. This experiment is configured with one NameNode and four DataNode, Table 2 for the specific planning of Hadoop environment.

TABLE 2 graphs and HDFS node configuration information

	master	**JobTracker/TaskTracker**
Mapreduce	slave1	TaskTracker
	slave2	TaskTracker
	slave3	TaskTracker
	master	**NameNode/DataNode**
HDFS	slave1	DataNode
	slave2	DataNode
	slave3	DataNode

3.3 SIMILARITY MEASURE METHOD

This paper uses the modified method of similarity measure in the map function to achieve the effect of normalized processing. Traditional k-means algorithm is used in the graphs, the map function defined in the two samples x_a, x_b similarity is the use of Euclidean distance, the smaller the $s(x_a, x_b) = \sqrt{\sum_{j=1}^{n}(x_a - x_b)^2}$, smaller $s = (x_a, x_b)$ shows that the greater the similarity between samples. Sample calculation and $s = (x_a, x_b)$ size of each centre, and clustering to the smallest clusters of $s = (x_a, x_b)$ distance class. In order to achieve the result of the normalized, modify the judgment criterion of the map function, to redefine the sample similarity distance is:

$$s'(x_a, x_b) = \sum_{j=1}^{n} \frac{1}{1 + |x_a - x_b|}. \quad (1)$$

Similarity between each attribute was defined as the reciprocal of the Manhattan distance plus 1, the greater the value of $s = (x_a, x_b)$ shows the greater the similarity between the sample data. By improving the similarity measure of $s = (x_a, x_b)$ calculated data sample and each centre distance, the result value, the greater the explain data samples is more similar with the centre. Due to the improved similarity measure $s = (x_a, x_b)$ to map samples of each attribute to between 0 and 1, guarantee the contribution of each attribute function in the same frame of reference, have the effect of the normalized. Such clustering result also has more explanatory.

4 Parallel algorithm design

4.1 CONSTRUCTION OF THE CLUSTER

Cluster is the master node and slave nodes distribution on different computers. In the practical application of Hadoop cluster scale is compared commonly big, but the main purpose of this paper is to validate the Hadoop in the usability of the website user data clustering, this simulation environment for the four nodes Hadoop cluster, transplanted clustering algorithm into Hadoop platform.

4.2 DESIGN AND IMPLEMENTATION OF PARALLEL ALGORITHM

In the Hadoop platform the key step for realizing the parallel Kmeans algorithm is to design the Map function and a Reduce function. Every process of Mapreduce is equivalent to a serial clustering algorithm in an iterative process. The Map function is to get the data object distance to the centre node, and distributing the data object to the nearest cluster class, and marking the category ID. The Reduce function completes new centre in the same cluster class value calculation. Relatively new clustering centre, compared with the previous clustering centre, when the error is less than the convergence value, the clustering process is over, otherwise the circulation process of Mapreduce. For the convenience of the recording and processing the data and Mapreduce calculation model uses the line form for storage, as there is no correlation, piece of data to be processed data line can be shard. To ensure the independence of the clustering process each iteration the data can be distributed to store the data node.

4.2.1 The map function design.

The main content of the Map function is calculated each data to all the selected centre distance, and put each data tag to the centre of the shortest distance, belong to the same data centre is a bunch of classes. The Map function is < key, value > way to input and output. The input data is the centre of the previous iteration (or the centre of the random selection) and all the sample data. Input function < key, value > object relative to the corresponding is the key data in the data file offset of the starting point and the value corresponding to the data object coordinate values of each dimension. Output data is each data object belongs to the ID, the output function < key, value > value or represent data objects in the coordinates of each dimension, and the key value indicates that the clustering centre of the data object. The Map function to realize pseudo code:

```
void map(LongWritable key,Text value){
mis_distance=getEuclideanDistance(point,cluster[0]);
for(int i=0; i<k; i++){
If(getEuclideanDistance(point, cluster[i])<mis_distance){
mis_distance=getEuclideanDistance(point, cluster[i]);
  currentCluster_ID=i;
  }
}intermediate_output(currentCluster_ID, point);
}
```

4.2.2 Reduce function design

The main content of the Reduce function is to the same cluster the data averaged class, get a new centre, if the centre of two adjacent results don't happen deviation, clustering results are produced. If the result deviation, this time the Reduce output centre as the initial centre of the next iteration. Reduce function of the input is the output of the Map function, the results of the same key value is assigned to the same Reduce calculation (i.e., the same cluster class assigned to a Reduce in). Corresponding form input function < key, value > for < cluster ID of the list (belong to the centre of the data objects) >, calculate the same in each Reduce the number of the class and each component and cluster computing the mean of each component of the clustering centre as a new file. Output function < key, value > for < > cluster ID, sample vector.The Reduce function implementation of pseudo code:

```
void reduce(Writable key, Iterator<PointWritable> points){
long num=0;
Float sum=0.0f;
While(points.hasNext()){
   PointWritable current_point=points.next();
   num+=current_point.getNum();
   for(int i=0; i<dimension; i++)
   sum[i]+=current_point[i];
   for(int i=0; i<dimension; i++)
   mean[i]=sum[i]/num;
}result_output(key,mean);
}
```

5 Similarity measure experiment and analysis

5.1 CLUSTERING CRITERION

Clustering analysis of the target is to belong to the similar research object into a class, belong to the same object of a class as similar as possible, and not the same kind object is different, as far as possible, the basic clustering criterion contains three functions.

5.1.1 The error sum of squares criterion function.

Data sets $R=\{r_1,r_2,r_3,...,r_n\}$, by clustering into *k* clusters, namely $R_1,R_2,R_3,...R_k$, each class contains data $m_1,m_2,m_3,...,m_k$ for a number of clusters, defined error sum of squares criterion function is:

$$j_a=\sum_{j=1}^{k}\sum_{n=1}^{m_j}\left\|r_n^{\ j}-c_j\right\|^2, \tag{2}$$

r_n^j of them belong to the same cluster class *j* of sample data. While c_j said *j*-th clusters mean all the samples in the class, the class cluster centre, its representation is:

$$c_j=\frac{1}{m_j}\sum_{j=1}^{m_j}r_j,\ j=1,2,3,...,k. \tag{3}$$

Error variance criterion function mainly calculation belong to the same cluster samples of a class and the class of cluster to Euclidean distance to the centre of the square, when the smaller the value of j_a, suggests that cluster-heads data between difference is smaller, the clustering effect is good. In the process of clustering iterations, similar data will be allocated according to the judgment of the distance to the same cluster, j_a function present a descending trend. However, only use this a judgment standard is not enough, the error sum of squares criterion suitable for sample data density is bigger, small differences between the clusters of judgment, in the case of within the cluster sample difference is very big, the error sum of squares criteria often cannot render good effect [11].

5.1.2 The weighted average of the sum of squares of the criterion function

This function is shown by the following:

$$j_b=\sum_{j=1}^{k}p_j f_j^{\ *}. \tag{4}$$

The p_j is the prior probability, of the total number of samples for *m*, assigned to the *j*-th class cluster of number for m_j, is the representation of a prior probability method is:

$$p_j=\frac{m_j}{m},\quad j=1,2,3,...,k \tag{5}$$

and $f_j^{\ *}$ said *j*-th cluster-heads mean value of the square of the distance between two objects, because m_j number within the cluster is, the combination of two number is $m_j\left(m_j-1\right)$, expression is:

$$f_j^{\ *}=\frac{2}{m_j(m_j-1)}\sum_{r\in R_j}\sum_{r'\in R_j}\left\|r-r'\right\|^2. \tag{6}$$

In view of the error variance criterion function cannot very good judgment sample data of markedly different defects, weighted average of the sum of squares of good make up for it. Rule of the main computing the sum of squared distance between classes in the same cluster sample. As the clustering iterations, similar samples gathered in the same cluster, cluster sample within the distance between the smaller and smaller, the weighted average of the sum of squares of the criterion function said local area density, will present a downward trend.

5.1.3 The distance between the class and the criterion function

The above two criteria are judgment within the cluster, the similarity between data, and the distance between the class and the criterion function is more focused on different types of separation degree, the rule of the well of the distance between each cluster are described, the expression is as follows:

$$j_c=\sum_{j=1}^{k}\left(c_j-c_{all}\right)^T\left(c_j-c_{all}\right). \tag{7}$$

Expression of c_j said all the samples in the class is the first j cluster averages, c_{all} said average of all the sample data. In the process of clustering iterations, each cluster degree of dissimilarity between more and more obvious, the distance between the class criterion function present a rising trend.

Taken together with the increase of clustering iterations, the error sum of squares criterion function and

weighted average of the sum of squares of the criterion function as class data cluster distance more and more close, property is more and more similar, function values can present a downward trend, show the same kind object difference as small as possible. And the distance between the class criterion function with data between clusters of separation, function values can present a rising trend, show differences between different objects as large as possible.

5.2 THE RESULT OF THE EXPERIMENT

This experiment from UCI Machine Learning Repository site selection of the iris data set, wine data set, the data set and the vehicle data sets upload the four sample data to hadoop distributed file system. Then the graphs programming under the framework of Kmeans algorithm to cluster analysis, and use and square error criterion function, weighted average of the sum of squares of the criterion function. The distance between the class and criterion function on the process of clustering analysis, observation is related to the changes in the process of iteration function, verify the reliability of the parallel clustering algorithm.

The iris sample set a total of 150 data, each data contains 4 kind of attribute, the whole data set can be divided into 3 clusters; Wine sample set a total of 178 data, each data contains 13 kinds of attributes, the whole data set can be divided into 3 clusters; Seed data samples with 210, each sample has eight kinds of attributes, samples can be classified into 3 clusters; Vehicle data samples with 94, each sample has 18 kinds of attributes, samples can be classified into four clusters. Because the Kmeans algorithm is randomly selected from the initial value, different initial value selection may get different clustering results, so this paper 20 times for each criterion function clustering operation, a randomly selected as the experimental results. At the beginning of the iterative function change is more obvious, therefore this thesis excerpts from the first five iterations as trend analysis. Table 3-6 of iris respectively, wine, seed, vehicle data aggregation class effect.

TABLE 3 Iris data aggregation class effect

1	8.580×10^{7}	3.155×10^{4}	2.068×10^{5}
2	6.815×10^{7}	2.821×10^{4}	2.832×10^{5}
3	7.233×10^{7}	2.821×10^{4}	2.847×10^{5}
4	7.045×10^{7}	2.773×10^{4}	2.823×10^{5}
5	6.814×10^{7}	2.729×10^{4}	2.854×10^{5}

TABLE 5 Seed data aggregation class effect

Number of iterations	Error sum of squares	Weighted average sum	Distance between the class sum
1	6.045×10^{4}	9.971	30.261
2	4.672×10^{4}	8.874	30.921
3	3.438×10^{4}	7.162	31.992
4	2.467×10^{4}	6.448	31.968
5	2.243×10^{4}	5.973	31.594

TABLE 6 Vehicle data aggregation class effect

Number of iterations	Error sum of squares	Weighted average sum	Distance between the class sum
1	1.051×10^{7}	2.047×10^{4}	1.019×10^{5}
2	6.991×10^{6}	1.324×10^{4}	1.140×10^{5}
3	7.115×10^{6}	1.184×10^{4}	1.309×10^{5}
4	6.475×10^{6}	1.137×10^{4}	1.440×10^{5}
5	5.798×10^{6}	1.132×10^{4}	1.468×10^{5}

By the form can be found on the four sample data shows that with the increase of the number of iterations. Clustering similar sample data set in the same class makes the error sum of squares criterion function. The weighted

average of the sum of squares of the function presented a decreasing trend, and differences between class and class increases gradually, the distance between the classes and functions presented an increasing trend. But the three functions is not monotone changing, in the process of clustering iterative search criterion function of the uncertainty of the optimum path, the criterion function results may fluctuate, but the overall trend in line with the desired results. At the same time can also be observed in three previous iterations, the change of the function value is relatively obvious, to late function value change is small, the clustering results. The experiment proves that the graphs under the programming model of parallel Kmean algorithm, has good clustering effect. Under the Hadoop cluster composed of four machines respectively samples of different sizes of data clustering analysis, proves that the parallel algorithm of Hadoop platform on the large data applications better speedup and scalability.

Abstract

In this paper we investigation the scope of capacity for different EDAs to successfully solve problems, which concern to the mutual effects among the variables. More specifically, we study the learning restrictions that different EDAs confront to solve problems, which can be expressed by some ADFs. The research is conducted in the worst situation. The sub-functions in the ADFs are the same deceptive functions. We think that the capacity for this kind of algorithm are primarily influenced by the probabilistic model they depend on. We employ three different kind of EDAs so as to investigate the effect that the complexity of the probabilistic model has on the behave of the algorithm. Because the population size is crucial for EDAs, we use different population sizes in the experiments. Nevertheless, the results indicate that, in general, enlarge population size is not useful to solve more complex problems.

Keywords: EDAs, capacity, complexity, problem structure, probabilistic model

1 Introduction

Estimation of distribution algorithms (EDAs) [1-4] are a new kind of evolutionary algorithms (EAs) that use probabilistic models instead of the typical genetic operators used by genetic algorithms (GAs) [5, 6]. The features of the search space in EDAs are extracted by machine learning methods. In EDAs, employing a probabilistic model to represent the collected information which is used to generate new individuals later. By this way, probabilistic models can lead the search to hopeful areas of the search space.

Mathematically, an optimization problem can be seen as the minimization or maximization of a given function. Thus, optimization problems can be formulated as,

$$x^* = \arg\max_x f(x), \tag{1}$$

where $f: S \to \mathrm{R}$ is called the objective function or fitness function, $x = (x_1, \ldots, x_n) \in S$ is a candidate solution of the problem and S is named the problem space. In most cases, the optimum x^* is not unique. In this paper, the problem space S is an n dimensional discrete space.

Because the EDAs [2, 4] can capture the structure of the problem, EDAs are considered to be more efficient than GAs. In EDAs, the specific interactions among the variables of solutions in the problem are taken into mind. In evolutionary algorithms, the interactions are display implicitly in mind; whereas in EDAs, the interrelations are showed explicitly through the joint probability distribution associated with the individuals of variables selected from each generation. The probability distribution is calculated according to a population of selected candidate solutions of previous generation. Then, offsprings are sampled from this probability distribution generate. Neither crossover nor mutation has been used in EDAs. Figure 1 displays the Pseudo-code of Estimation of Distribution Algorithms.

networks is one of the models that has been widely used in EDAs. One of the advantages of EDAs that employ these kinds of models is that the complexity of the learned structure relies on the characteristics of the selected individuals. Moreover, the analysis of the models learned during the search can provide useful information about the problem structure.

How the characteristic of the search space are reflected in the learned probabilistic models is another related and important issue in EDAs. This issue has received special attention from the EDA community, and is essential to understand the mechanisms that enable EDAs to efficiently sample from the problem space during the search process. However, the question of analysing the relationship between the problem space and the structure of the learned probabilistic models becomes more and more difficult because of the next two main reasons: the search process is random in the EDAs, and the methods used when learning the models can only detect approximate, suboptimal, structures.

To investigate the effect that the complexity of the probabilistic model has on the behave of the algorithm, we employ three different implementations. Firstly, an EDA which is called univariate marginal distribution algorithm (UMDA) [7] that is considered independent among the variables, secondly, an EDA which is called EDAdt [8] uses a dependency-tree model every generation and last, an EDA which is called estimation of Bayesian networks algorithm (EBNA) [9,10] uses Bayesian networks. Because the population size is crucial [11] for EDAs and particularly when the used probabilistic model is Bayesian networks, we employ varying population sizes.

The experimental results indicate that the ability of EDAs to solve the testing functions is lost quickly when the number of sub-functions exceeds a certain value in the objective function. This threshold of behave indicates a obvious phase-transition phenomenon that clearly delimits the frontiers of effectiveness. The experimental results also indicate that the ability to learn structures is very important to extend the restrictions of successful EDA implementations. However, EBNA displays a tremendous decreasing of performance because the learning method cannot build more sophisticated models. Moreover, according to the experimental results, the learning of unrestricted Bayesian networks requires a huge computational cost for solving the problems. Therefore, in order to solve the problems, the complexity of the models should grow exponentially along with growth of the number of sub-functions.

2 Probabilistic models

The probabilistic model associates to the qualitative and quantitative structure determined by the probability function. Though the EDAs could employ any kind of probabilistic model, the widely used models are those that show their qualitative component by a graph. Especially, one kind of models that has been widely used in EDAs are Bayesian networks.

Bayesian networks [12-14], which is called belief networks are a kind of probabilistic graphical model. This kind of probabilistic models is one of very popular paradigms that can deal with probability distributions efficiently in modelling uncertain information. The domain of expert systems is one of the most important sources for the development of Bayesian networks. Moreover, in the past few years, Bayesian networks have obtained considerable attention in domain of the machine learning. As a result of this attention, more and more papers and tutorials have appeared. Thus, besides expert systems, Bayesian networks are also applied in classification problems, bioinformatics and optimization.

Bayesian networks are the product of associating probability and graph theory [15], similarly with any other probabilistic graphical model. The graphical consist of the model encodes a number of conditional independences related to the probability distribution. Let $X=(X_1,\ldots,X_n)$ be an n dimensional discrete random variable. A Bayesian network is a graphical expression of the factorization of the joint probability distribution for X, $p(X=x)$, where $x=(x_1,\ldots x_n)$ is an assignment of the random variable X. More specifically, a Bayesian network can be expressed as a pair (s,θ_s)s where s is a directed acyclic graph that is model structure and θ_s is the set of parameters associated to the structure that is model parameters. The structure s determines the set of conditional dependences among the random variables of X. According to the structure s, the joint probability distribution $p(x)$ can be factorized by means of marginal and conditional probability functions. More specifically, the probability distribution factorizes according to the graph as,

$$p(x)=\prod_{i=1}^{n} p(x_i \mid pa_i), \tag{2}$$

where pa_i denotes a value of the variables Pa_i that is the parent set of X_i in the graph s.

The local probability distributions in the factorization are those which is induced by means of the product that appears in Equation (2). We suppose that these local probability distributions depend on the parameters $\theta_s=(\theta_1,\ldots,\theta_n)$. So Equation (2) could be rewritten by specifying the parameters:

$$p(x \mid \theta_s)=\prod_{i=1}^{n} p(x_i \mid pa_i,\theta_i) \tag{3}$$

Suppose that the variable X_i has r_i possible values, thus, the local probability distribution $p(x_i \mid pa_i^j,\theta_i)$ is an unbounded discrete distribution:

$$p(x_i^k \mid pa_i^j,\theta_i)=\theta_{ijk}, \tag{4}$$

where $pa_i^1,\ldots,pa_i^{q_i}$ represent the q_i possible values of the parent set Pa_i. The parameter θ_{ijk} denotes the probability of variable X_i which takes in its *k*-th value, at the same time, the set of its parents' variables takes in its *j*-th value. Therefore, the local parameters are determined by $\theta_i = ((\theta_{ijk})_{k=1}^{r_i})_{j=1}^{q_i}$.

In order to look for a Bayesian network [16, 17], which can make us to represent and deal with the uncertain knowledge of a specific field, setting both the structure and the parameters is very necessary. The structure and conditional probabilities that is necessary for describing the Bayesian network can be provided either externally by experts, by machine learning from datasets or by mixing both of these methods. In this paper. We mainly focus on the second method. Besides, when the structure has been automatically learned, it can provide us with perceptions into the interactions between the variables of the field.

The learning step can be separated into two subtasks that are structural learning and parameter learning [18-20]. Although there are different approaches to learn the structure of a Bayesian network, we mainly focus on the so-called score plus search method. This kind of methods copes with the structure learning as an optimization problem. Thus, the steps of learning a Bayesian network can be expressed as follows. Given a data set D containing N cases, $D=\{x_1,\ldots,x_N\}$, finding the structure s^* such that,

$$s^* = \arg\max_{s\in S^n} g(s,D), \tag{5}$$

where $g(s,D)$ is the score which measures the quality of any given structure s related to the data set D, and S^n is the set of all possible directed acyclic graphs (DAG) which have *n* nodes. A number of relevant and used heuristic techniques such as greedy search, simulated annealing, particle swarm optimization, genetic algorithms and ant colony optimization have been used in this task.

If score can be decomposed in presence of complete data sets, it is the one of the desirable character. These scores can be decomposed in sub-scores related to every node X_i and its parents Pa_i in the structure s. Formally, we can express a decomposable score as:

$$g(s,D) = \sum_{i=1}^{n} g_D(X_i, Pa_i), \tag{6}$$

where the g_D is the sub-score function. As a result of the decomposability, it is computationally more efficient when the local search is carried out, because when we add an arc into the network, it is only necessary to evaluate the set of nodes involved by this change.

When we have defined a score to assess Bayesian networks, we have to run a search process to look for the Bayesian network, which can return the best score given the data.

In practical applications, we must to look for an suitable model structure [21-25] as soon as possible. Thus, a simple learning method, which can find a relatively good structure, even though it is not best, is preferred. There are a number of learning methods, which can be employed for this task. However, a specific search algorithm which is called Algorithm B [19], which is typically used by most of Bayesian network based EDAs.

Algorithm B is a greedy search algorithm and its pseudo-code is presented in Figure 2, where D is a data structure which contains the information needed to deal with the candidate arcs which should be added into the network. At the beginning, Algorithm B starts from an arc-less structure, which represents independently among the variables, and at each iteration, an arc is added into network that can increase the score greatly. The algorithm stops when no arc that can increase the score any more, can be added into the network.

1 begin with an arcless strcture
2 compute $D[X_j \to X_i] = g_D(X_i, X_j) - g_D(X_i)$ for all distic X_i, X_j
3 **do**
4 find the largest $D[X_j \to X_i]$, and add an arc from X_j to X_i in the structure
5 $D[X_j \to X_i] = g_D(X_i, Pa_i \cup X_j) - g_D(X_i)$ for all disctinct X_i, X_j not belonging to Pa_i
6 $D[X_j \to X_i] = -\infty$
7 **until** every $D[X_j \to X_i] < 0$

FIGURE 2 Pseudo-code for Algorithm B

When we have got a Bayesian network by learning, this model could provide us with detailed probabilistic information which we are interested in. Usually, the information, which the researcher wants to know is the probability of some events on the basic of special observations. Generally speaking, the probabilities which we are interested in, are not reposted in the Bayesian network obviously. It is necessary to compute in order to obtain them,. This course is called probabilistic inference and it is usually an NP-complete problem.

Emulation of Bayesian networks, which is also named stochastic sampling, can be regarded as an option to the exact inference. The Emulation of a given probabilistic graphical model requires to get a sample from the probability distribution for X which the model encodes. Next, the marginal and conditional probabilities involved can be calculated from the sample.

For our goals about EDAs, the intension of the emulation of Bayesian networks is to get a new population in which the probability relations among the random variables of the network are potential. Specifically, for the purpose of sampling from the Bayesian network, the sampling method which we employ is forward. The variable must be sampled after all its parent variables have

been obtained. This approach is named probabilistic logic sampling (PLS). Figure 3 presents a pseudo-code of this approach.

```
1   π ← ancestral ordering of the nodes in the baysian network
2   for j = 1 to N
3     for i = 1 to n
4       x_{j,π(i)} ← randomly generate a value form p(x_{π(i)} | pa_{π(i)})
5     done
6   done
```

FIGURE 3 Pseudo-code of the probabilistic logic sampling method

3 Testing functions

In order to study the performance of EDAs when the complexity of the function grows, we handle additively decomposable functions (ADFs). This kind of functions are regularly employed by researchers [26-28]. As everyone knows, a number of optimization problems investigated recent years could be modelled by ADFs. The model of function employed in this paper, in which new sub-functions are one by one added, could be seen as a system that grows its complexity with the time, because new interactions appear among the variables [29].

We define ADFs in a general form. Let $S=\{0,1\}^n$ be the problem space, a fitness function $f:S\to R$ is decomposable if it can be expressed as a sum of sub-functions of lower dimension,

$$f(x)=\sum_{c_i\in C} f_i(c_i), \tag{7}$$

where $x=(x_1,\ldots,x_n)\in\{0,1\}^n$ and $C=\{c_1,\ldots,c_l\}$ is a set composed of distinct sub-sets $c_i\subseteq\{x_1,\ldots,x_n\}$. Moreover, we suppose that set c_i and c_j are distinct and not include each other. This kind of functions is also featured by its order *k*, which is determined by the size of the largest subset in C.

In this paper we employ detailed cases of this general kind of functions. Firstly, all the sub-sets in C have three variables, that is to say $k=3$. Thus, C includes all the sets of distinct sub-sets, which are selected from all the $C(n,k)$ possible sub-sets of variables. Secondly, all the sub-functions f_i are the same deceptive function f_{3dec} which is proposed by Goldberg. Given $u(y)=\sum_{i=1}^{k} y_i$, where $y\in\{0,1\}^k$, the function can be formulated as,

$$f_{3dec}(c_i)=\begin{cases}0.9 & for \quad u(c_i)=0\\ 0.8 & for \quad u(c_i)=1\\ 0.0 & for \quad u(c_i)=2\\ 1.0 & for \quad u(c_i)=3\end{cases}. \tag{8}$$

From standpoint of the EDA, the advantages of the fitness functions that we use are evident [30-32]. First of all, independently of the number of sub-functions, we all time know the globally optimal solution, which is with all ones. Secondly, the deceptive method generates strong interactions among the variables which belong to every sub-function.

About the functions f_{3dec}, when they are managed without overlapping among the set of variables, we get the function Deceptive3. This function was designed in the background of genetic algorithms with the purpose of analysing their restrictions. Thus, in this paper, the function will be a helpful reference so as to analyse the restrictions of behave in EDAs. At present, deceptive separable functions are widely employed to analyse evolutionary algorithms.

For the sake of raising the complexity of the functions step by step, we use a simple method. First of all, we create a series of objective functions in which every new function puts one more sub-function into the previous one. This series of functions is determined by the ordered set $C=\{c_1,\ldots,c_l\}$. This ordered set is composed of l different sub-sets of variables which are randomly taken from all the $C(n,k)$ possible combinations following a uniform distribution. Though we could add all the $C(n,k)$ different subsets in C, it will be not essential to get learning restrictions. Therefore, the *s*-th objective function in the list adds *s* sub-functions which are the first *s* sub-sets of variables in C. The *s*-th function can be formulated as,

$$f_s=\sum_{i=1}^{s\le l} f_{3dec}(c_i). \tag{9}$$

However, the ordered set C has a constraint. The join of the first n/k sub-sets equal to the whole set of n variables, constituting the function Deceptive3. Be aware that in the functions from $s=1$ to $s=n/k$, a number of the variables do not appear in any sub-function. In order to make these functions intact, we directly use the previously mentioned function u to include the set of variables $\{x\setminus\bigcup_{i=1}^{s} c_i\}$, which do not appear in the sub-function. This measurement is very helpful to investigate the univariate and bivariate EDA. Moreover, this separable function is helpful to indicate difficulty of a problem.

Finally, because of the random nature of the set C, we have produced for the experiments 100 different random instances of this kind of sets and the results presented are the average value from them. The entire set of experiments include three different problem sizes ($n\in\{24,48,72\}$) and the maximum number of sub-functions which is

determined by C, is $l = 200$. Moreover, for every possible function, we conduct ten independent EDA runs. The number of runs per instance is limited because of the high computational cost.

The intensity of interaction can be understood as a notion about the interdependences that appear among the variables of a problem. Though there are a number of different methods to estimate this notion, in the background of the present work, we suppose that the intensity of interaction is simply determined by the number of sub-functions contained in the objective function [33-35].

Moreover, in order to give a more direct measure of the intensity of interaction, we consider the frequency that every variable appears in sub-functions. For instance, in some ADFs, each variable appears in only one sub-function. Generally speaking, given s sub-functions with size k including n variables, we compute the expected number of variable appearing in sub-functions. It is formulated as,

$$\langle s \rangle = s\frac{k}{n}. \tag{10}$$

In order to demonstrate how the landscapes of the ADFs change along with the number of sub-functions increasing, we give a simple example in which the number of variables is 9 in Figures 4-7.

These figures shows changes of function value with four objective functions, which differ only in the number of variables. The solutions are sorted by the number of ones so as to supplying more intuitive graphs. For instance, the region with the number 4 is comprised of all the $C(9,4)$ solutions, which have 4 ones. Therefore, the region with the number 0 and number 9 only contains one solution. The two solutions play an important role in the kind of functions we employ, and thus, the solution with all zeros is emphasized with a circle and the solution with all ones, which is optimum is emphasized with two concentric circles.

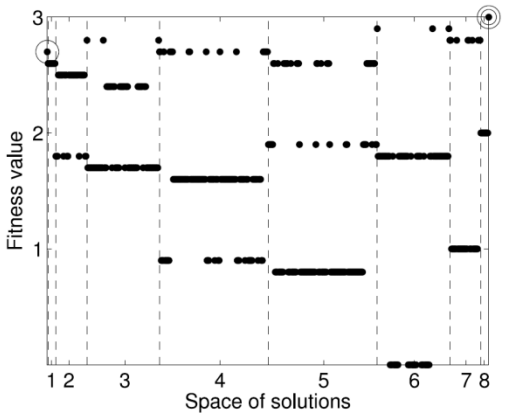

FIGURE 4 f_3, 3 sub-functions, $\langle s \rangle = 1$

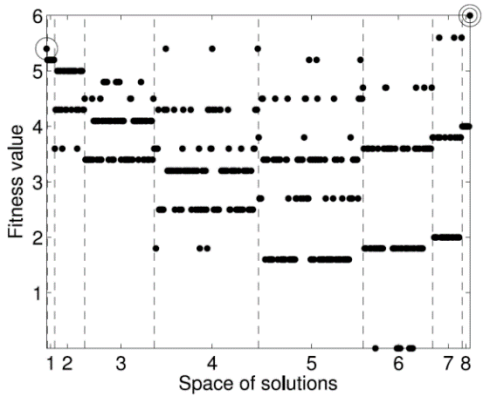

FIGURE 5 f_6, 6 sub-functions, $\langle s \rangle = 2$

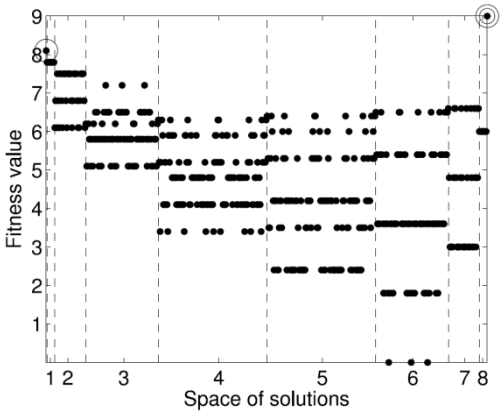

FIGURE 6 f_9, 9 sub-functions, $\langle s \rangle = 3$

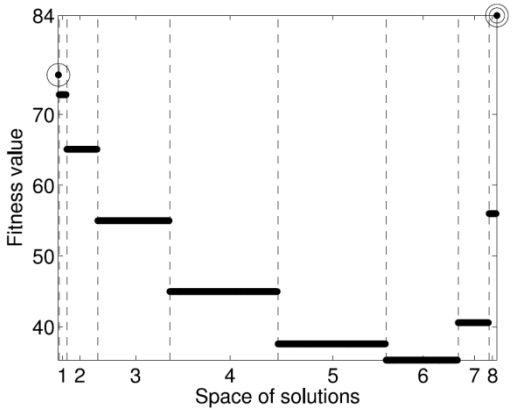

FIGURE 7 f_{84}, 84 sub-functions, $\langle s \rangle = 28$

In this part, for each function created, we compute the order of a possible related exact factorization. This computational process is a proximity to the exact factorization, which has minimum complexity. However, this process provides useful information about the complexity of the probabilistic models, and it is essential for an EDA to solve the created problems in the worst conditions. The orders of the used functions change as shown in Figure 8. This Figure presents when problem sizes is 3, the order change with the average number of sub-functions in which each variable appear. We begin from $\langle s \rangle = 1$, in this case it is the Deceptive3 function. The results show an exponential growth of the number of parameters related to exact factorizations and thus, the

complexity of these models rapidly becomes too high to manage. Even if having enough knowledge concerning the function, looking for this kind of probabilistic models is confronted with considerable computational restrictions. Moreover, if these factorizations were employed in an EDA, the population size should also grow with the complexity of the factorizations so as to get a robust behave of EDAs [36].

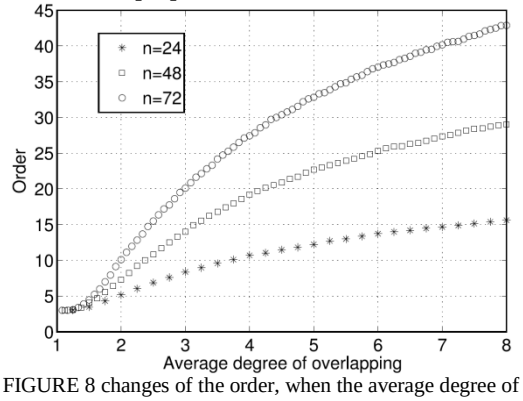

FIGURE 8 changes of the order, when the average degree of overlapping grows

4 Experimental results

In this part, we present experimental results. The relationship between the ratio of success and the number of sub-functions for each kind of algorithm gives in Figure 9, Figure 11 and Figure 13. The relationship between hamming distance to the best solution and the number of sub-functions for each kind of algorithm gives in Figure 10, Figure 12 and Figure 14. We only show the experimental results for the problems with $n = 72$ variables. The performance of the algorithms is alike for the three different problem sizes ($n \in \{24, 48, 72\}$) that we have used. Nevertheless, when the number of variables grows, the patterns are more obvious and clearer.

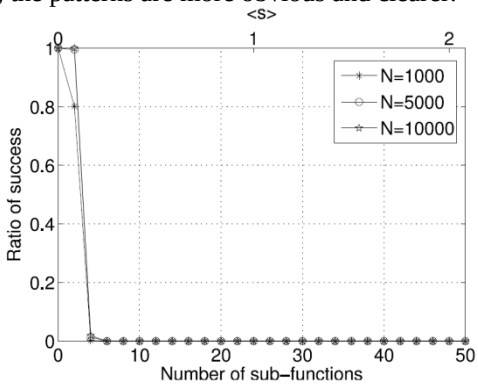

FIGURE 9 Ratio of success in UMDA

Generally speaking, by means of the descriptors employed in Figure 9 - Figure 14, we can obviously see the behave that different EDA implementations fails. The graphs exhibit a phase-transition effect when the interaction in the created problems exceeds a certain degree. However, this effect is especially remarkable in the graphs of ratio of successful runs, which fall off from 1 to 0 steeply after only adding very few sub-functions. Therefore, in UMDA and EDAdt, the number of sub-functions between total success and complete failure is within 2 sub-functions. For the EDA based Bayesian networks, though this algorithm also suffers a sudden fail, the conversion from 1 to 0 in the ratio of successful runs is relatively more gradual. concerning the hamming distance, it exhibits a more gradual change, which supplies complementary information concerning the quality of the solutions. For instance, though in Figure 9 the ratio of success can be equal to 0 when the number of sub-functions is 4, UMDA returns solutions which are near the optimum in hamming distance in Figure 10.

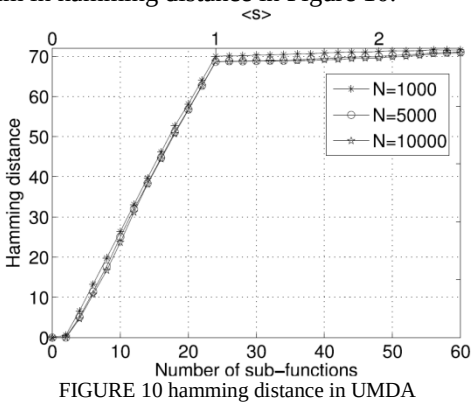

FIGURE 10 hamming distance in UMDA

From the results obtained from the experiment, we also achieve the understanding of the effects that the probabilistic models and the population size have on the EDAs when we solve problems with growing interaction. As anticipated, the probabilistic model employed in the EDAs has a determined influence on the scope of problems that it can solve. Therefore, UMDA begins to fail when the number of sub-functions is 2 in the objective functions, EDAdt can attain the equivalent level of Deceptive3 function and EBNA collapses between the ADFs and the functions with $\langle s \rangle = 2$.

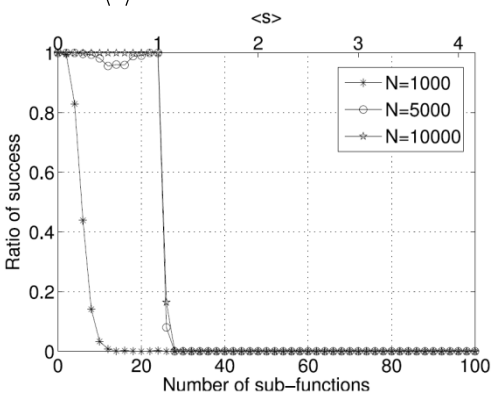

FIGURE 11 ratio of success in EDAdt

In addition, according to experimental results, if an EDA to can deal with more complex structural models, the population size has a more effect on the performance of the EDA. It is decisive to achieve a robust behaviour of EDAdt and EBNA, while UMDA is hardly affected by this parameter. As presented in Figure 11 and Figure 12, the smallest population size ($N = 1000$) is clearly inadequate,

therefore these algorithms cannot achieve a ideal performance.

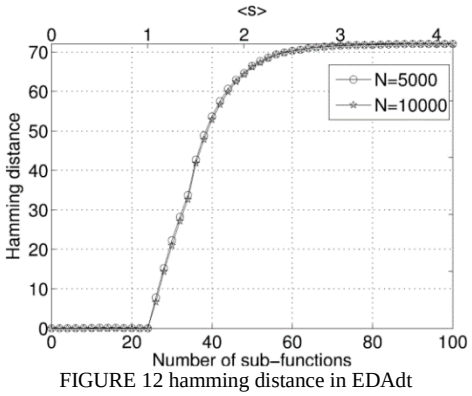

FIGURE 12 hamming distance in EDAdt

The greatest influence of the population size takes place in EBNA and it is reflected in the graphs shown in Figure 13 and Figure 14. However, even for EDA based Bayesian networks, this parameter exhibits a limited effect to overcome influence of threshold. This suggests that, though the population size is important to obtain a ideal behavior, growing this parameter is not an efficient way to solve the problems when the degree of interaction grows. In this respect, we can see in Figure 13 and Figure 14 that the different graphs tend to be closer as the size of the population grows.

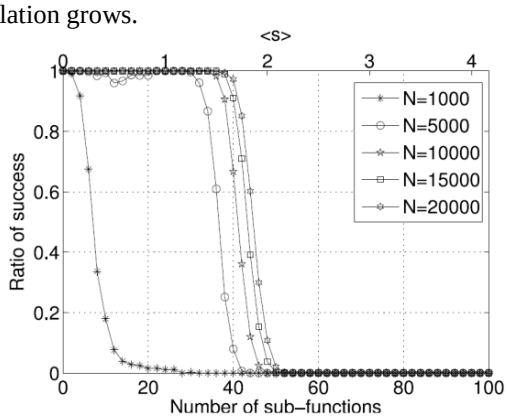

FIGURE 13 ratio of success in EBNA

From the graphs of hamming distance, we can see another phenomenon. when the interaction in the problem exceeds a certain extent, all EDAs only can find solution with all zeros. Thus, we could conclude that, from the aspect of efficiency, UMDA is the best choice to deal with the problems which exceed this critical threshold of difficulty. According to this viewpoint, and considering the whole scope of functions that can be created from $s=0$ to $s=C(n,k)$, EBNA exhibits better performance in a reduced sub-space. Be aware that Figure 9 - Figure 14 only presents the behaviour of the EDAs at the first ranks of difficulty. When n equal to 72 and *k* equal to 3, we could obtain in the fitness function up to $C(72,3)=59640$ sub-functions. Thus, the graphs only depict a small fraction of this number.

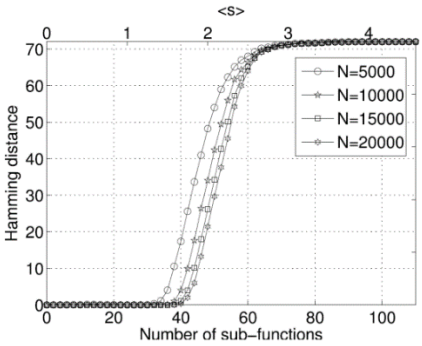

FIGURE 14 hamming distance in EBNA

From the experimental results given in Figure 9- Figure 14, we have observed that how the behave of different EDAs suddenly fails when the interaction among the problem variables exceeds a certain extent. The reason for this phenomenon is that UMDA and EDAdt are deficient in ability to learn models. Nevertheless, for EBNA, it is deserving to carry out a more thorough analysis of the reason of its failure. In order to do this, we consider the complexity of the Bayesian models learned from the experiment. We employ the order of the factorizations which is determined by these probabilistic models to assess their complexity. In Figure 15, we present the average maximum orders of the models learned from each execution.

Be aware that the influence of phase transition seen in Figure 13 and Figure 14 is associated with Figure 15. Therefore, EBNA starts to collapse quickly after the peaks in Figure 15, that is to say when the algorithm could not construct more complex models. Figure 15 indicates that the complexity of the Bayesian networks grows exponentially with the number of sub-functions so as to solve the problems. Be aware that when the learning method cannot construct the appropriate structures to solve more problems, the algorithm still spends a large number of computational resources on learning false models.

It is a question that what extent the behaviour mentioned above depends on the learning method, which need an thorough analysis. We argue that, in this worst situation, we will likely get a resembling performance for other approximate learning methods.

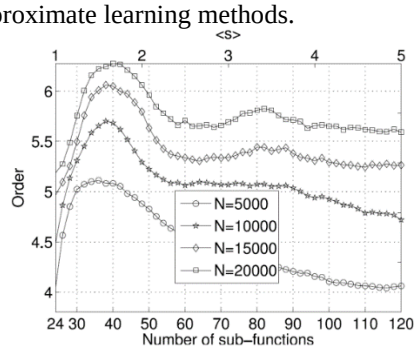

FIGURE 15 maximum orders of the models learned by EBNA

We compare the complexity of the learned structures with the complexity of the exact factorizations in Figure 16 and Figure 17. The curve shown in Figure 16 corresponds to the order of the exact factorizations, which were presented in Figure 8. However, in the graph, the number of

variables is only for $n = 72$ and curve is exhibited in relation to the number of sub-functions. We have used a circular mark so as to approximately indicate the region where EBNA fails. In Figure 17, we put the order of the exact factorizations and the order of the Bayesian networks obtained by the EDA together. The dashed line indicates the graph of the exact factorizations. In this Figure, we can observe that, when the EDA can run successfully, the maximum complexity of the models obtained is not less than the complexity of the exact factorizations. That is to say, when the EDA cannot learn the complexity of the models, which equals to the exact factorizations, it no longer solves more complex problems. The dashed line of the factorizations exactly separates the problems solved by EDA from the problems unsolved by EDA for every population size. Population size, which is insufficient may be the main reason to explain the bad behave in looking for the model structure.

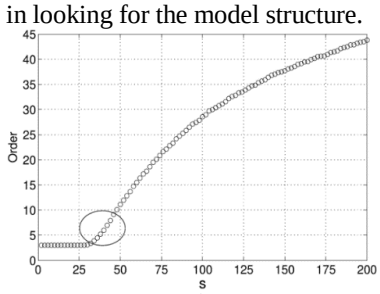

FIGURE 16 maximum orders of the models learned by EBNA

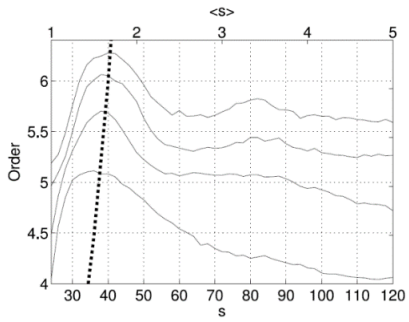

FIGURE 17 maximum orders of the models learned by EBNA

5 Conclusions

In this paper we have investigated the restrictions of behave that different EDA implementations confront when the interaction among the variables of the problem grows. We conduct the study by the employment of ADFs in which new sub-functions are added one by one. Therefore, the interaction can be measured by the number of sub-functions, which the objective function contains. In addition, we employ the separable deceptive function as a indication of problem difficulty so as to supply more perspicuous results. In the experiments, we have carried out three different type of EDA implementations. Because these algorithms only distinguish in the probabilistic model employed, the results indicate the influence that using more complex models has so as to solve a broader scope of problems. We have also employed different population sizes, which has been crucial so as to realize a potent performance in EDAs that base on Bayesian networks. Nevertheless, the results show that, generally speaking, growing this parameter is not useful to solve more difficult problems.

We have found that the EDAs fail with a phenomenon of phase transition when the number of sub-functions in the objective function grows in the worst situation,. The area in which EBNA collapses is between the separable deceptive functions and the objective functions with $2n/k$ sub-functions. The reason for the breakdown of the algorithm is that the EDA cannot obtain correct models. Once the EDA cannot to learn more complex models which is essential to solve more difficult problems, the algorithm fails. The complexity of the networks tends to grow exponentially so as to find the optimum needed for the algorithm. Nevertheless, exceeding a certain degree, the learning method cannot structure the suitable models to solve the problem and then, the algorithm collapses quickly. It implies that, when the degree of interaction exceeds a critical point, the learning of Bayesian networks may not be able to obtain the information needed to find the optimum from the population. Moreover, the relationship between the models learned by the EDA and the exact factorization indicates forceful computational restrictions because of the exponential increasing complexity of the structural essential to solve the problems.

The restrictions of effectiveness displayed in this paper are straight associated to the learning procedure of the algorithm. Nevertheless, these restrictions do not always have only one cause. We can confirm three different standpoints from which the learning restrictions in EDAs could be investigated:

1) restrictions of the learning either because the model needs a priori knowledge or because they learn approximate models with bounded complexity.

2) Even if we employ a desired learning method, there are efficiency restrictions because the complexity of models grows exponentially, which is disadvantage to solve the problems when the number of interactions grows.

3) Restrictions for the population either because of the deficiency of information that it includes to solve the problem or because this parameter should grow exponentially to supply an effective learning.

In general, we have investigated the concept of borders of EDA effectiveness concerning the extent of interaction of the problem. The main objective of this study is not to look for the best algorithm or negate any method but to comprehend which algorithms are the suitable for which problems.

Received 1 July 2014, www.cmnt.lv

Abstract

Firstly, this paper describes how the histogram analysis method pre-processes the images to be segmented. Then is makes a detailed analysis of the working principles and behaviour pattern of basic artificial fish swarm algorithm (AFSA); dissects the defects of AFSA in principle and proposes an improved AFSA with global convergence. Finally, it presents the main steps of image threshold segmentation method based on AFSA; compares the performances of AFSA with those of other intelligent algorithms and proves that this improved AFSA makes all-around improvements on image segmentation.

Keywords: Image Threshold Segmentation, Artificial Fish Swarm Algorithm

1 Introduction

Image segmentation divides an image into several mutually-disjoint areas according to certain rules and every area meets the consistency under the rules for convenience of the subsequent target measurement as well as classification and identification. Image segmentation needs to divide the input image into two or more sub-regions, which is exactly the top priority encountered in the design and realization of image analysis, the text character identification and automatic target acquisition. Nowadays, there have emerged several image segmentation methods, including threshold segmentation method, statistic segmentation method and clustering segmentation, however, none of them is a universal image segmentation method. Therefore, it plays a significant influence on the entire performance of the segmentation method whether the appropriate image segmentation method is chosen.

Swarm intelligence is the intelligent behaviour of a group, which is formed by the individuals with no or simple intelligence in certain way and the individuals in this group show complicated intelligent behaviours through collaboration. For example, when the small fish with limited capacities are attacked by big fish, they usually hold together to form a fish swarm quickly and move around the swarm center continuously to withstand the attack and minimize the loss. In case of lack of centralized control and understanding of global situation, swarm intelligence can accomplish complicated and difficult tasks, which provides a clue for people to solve large-scale and complexly-distributed problems [1]. In image-processing applications, swarm intelligent optimization algorithm is relatively weak in mathematical theoretical foundation and it lacks the theoretical analysis in a general sense. When different swarm intelligent optimization algorithms are used in specific image processing, the parameters involved in these algorithms are usually determined by experience without any specific theoretical basis.

In order to improve the various shortcomings of AFSA, this paper has come up with an improved multi-behaviour AFSA with excellent global convergence after analysing and investigating the research results of other scholars. This algorithm has absorbed the advantages of other improved algorithms [2]. For instance, it optimizes the step size and horizon by using self-adaptive theory; increases the artificial fish behaviours such as jump and devour and makes distinct and all-around improvements over the basic AFSA. Therefore, it enhances the self-adaptive ability and convergence precision, accelerates the convergence time and avoids local extremum in searching global optimum [3].

2 The image pre-processing

Due to digital image acquisition and channel transmission, the images we obtain usually have noises, which may interfere the ornamental value of the images and even directly affects the subsequent image characteristics extraction, target measurement and target identification. Considering the influence of image noise, we reconstruct the images by using the characteristic of wavelet domain after multi-level wavelet transform, namely "the highest low-frequency coefficients and high-frequency coefficients have fewer noises", and so we can obtain enhanced noise-suppressing images of the original images. Then, the segmentation threshold to be determined shall be located between the two peaks of the

* ***Corresponding author*** e-mail 648357216 @qq.com

enhanced image histogram and its value shall be similar to the segmentation threshold of the enhanced image.

Assuming that the two peak values of the enhanced image histogram are *a* and *b*, narrow the distribution range of the threshold and design the objective function of threshold segmentation according to the following steps.

(1) Decompose the image to be segmented with three-level sym5 wavelet and proceed wavelet reconstruction by the decomposed 3rd-level low-frequency and high-frequency coefficients to obtain the noise-suppressing enhanced image.

(2) Analyze the histogram of the enhanced image; calculate the average grey level $\overline{c}$ and get the grey level *a* with the biggest possibility within $[0,\overline{c}]$ and the grey level *b* with the biggest possibility within $[\overline{c}+1,L-1]$. Then the threshold distribution range is $[a,b]\in[0,L-1]$ and $L=256$ is the grey level of the grey-level image[4].

(3) Segment the objective function by using OTSU according to the two-dimensional histogram information of the enhanced image and neighbourhood mean-value image.

3 The improved mechanism of fish swarm algorithm

Although AFSA has the merits like undemanding objective function value, greatly random parameter determination and quick convergence rate, improvements need to be made somewhere. When the optimization region of the algorithm is big or the change is relatively flat, the algorithm searching speed is becoming slow and the convergence performance decreases; the convergence speed is quick in the initial stage and it becomes slow in the later phase; optimization precision is subject to the randomness of horizon and step size so that it is difficult to get precise solutions [5].

3.1 THE IMPROVEMENTS OF ARTIFICIAL FISH SWARM BEHAVIORS

In the basic AFSA, assuming that there are *N* artificial fish in the search region and the *i*-th represents a feasible solution vector, $X_i=\left(x_1^i,x_2^i,\ldots,x_D^i\right)$ (D is the dimension). Then assuming that $X_i(t)$ is the current state of the artificial fish and (*t*+1) is the next status, the artificial fish will implement one of the four behaviours according to the current status in every iteration; update its ego state and add an added vector $\Delta X_i(t+1)$ on the basis of the original status X_i(t); therefore, the position update formula of the artificial fish in AFSA is described by using the following formula:

$$\Delta X_i(\mathrm{t+1})=\mathrm{Rand}()\bullet\mathrm{Step}\bullet\left[X_{next}(\mathrm{t+1})-X_i(\mathrm{t})\right], \quad (1)$$

$$X_i(\mathrm{t+1})=X_i(\mathrm{t})+\Delta X_i(\mathrm{t+1}). \quad (2)$$

In the above formula, Rand() is a random number within 0 and 1 and Step is the step size of the artificial fish. After every iteration, the artificial fish update the ego status according to the above formula [6].

3.1.1 The improvements of feeding

Assuming that (*t*) is the current status, $Y_i(t)$ is the function value of the current status $X_i(t)$; the next status is X_i(t+1) and X_j(t) is a randomly chosen status of its horizon. And the expression formula is as follows:

$$X_j(\mathrm{t})=X_i(\mathrm{t})+Visual\bullet Rand(). \quad (3)$$

In searching the minimal value, if $Y_i(t)>Y_j(t)$, then the artificial fish moves towards the vector sum direction of X_j and the global optimal position and the expression formula is as follows:

$$X_i(\mathrm{t+1})=X_i(\mathrm{t})+Visual\bullet Rand(). \quad (4)$$

3.1.2 The improvements of clustering

Assuming that (*t*) is the current status of the artificial fish, search the number of its companions n_f and the central position $X_c(t)$ within its horizon. If $Y_c(t)n_f<\delta Y_i(t)$, it is indicated that its neighbourhood centre has higher food concentration and low congestion degree and the artificial fish moves a step size towards the vector sum direction of the global optimal position X_{best} and the central position. If (*t*) $n_f>\delta Y_i(t)$, then the artificial fish implements the feeding [7].

3.1.3 The improvements of rear-end

Assuming that X_i is the current status of the artificial fish, search the smallest companion X_k(t) among the companions Y_k(t) within horizon. If $Y_K(t)\bullet n_f<\delta\bullet Y_i(t)$, it is shown that the status of the companion X_k(t) has higher food concentration and low congestion degree and then the artificial fish moves one step towards the vector sum of X_k(t) and the global optimal position X_{best} with its expression as follows. If not, the artificial fish implements feeding.

$$X_i(\mathrm{t+1})=X_i(\mathrm{t})+\left(\frac{\left(X_k(\mathrm{t})-X_i(\mathrm{t})\right)+\left(X_{best}-X_i(\mathrm{t})\right)}{\left\|\left(X_k(\mathrm{t})-X_i(\mathrm{t})\right)+\left(X_{best}-X_i(\mathrm{t})\right)\right\|}\right)\bullet Step\bullet Rand(). \quad (5)$$

3.1.4 The introduction of jumping

After several continuous iteration, if the objective function value of the optimal artificial fish is smaller than the pre-set value eps, then randomly choose some artificial fish and set their parameters with the expression formula as follows.

$$X_i(\mathrm{t+1})=X_i(\mathrm{t})+\beta\bullet visual\bullet Rand(). \quad (6)$$

In this formula, β can be either a parameter of a mutation function.

3.1.5 The introduction of devouring

We have increased a new fish swarm behaviour, devouring. In this new fish swarm movement mode, the artificial fish with low objective function value are usually considered as weak artificial fish because they have little influence on the algorithm performance. These weak artificial fish will be eliminated by the system after some iteration, which is just like they are devoured by big fish. Because these artificial fish which are eliminated are weak, they have little influent on the optimization capacity of the algorithm; thus reducing its complexity.

The specific behaviour description is as follows: in calculating the minimum, if the objective function value of a certain artificial fish is bigger than the set function value T_value after n continuous iteration, then the system will automatically release the system space occupied by this artificial fish and reduce the total amount of the artificial fish. Therefore, this artificial fish will not involve the subsequent iteration. Likewise, the maximum can be calculated [8].

3.2 THE IMPROVEMENTS OF PARAMETERS

The horizon and step size of the artificial fish in the basic AFSA are always fixed, which may lead to the slow convergence speed due to the undersized step size in the initial phase and the oscillation phenomenon caused by the oversized step size in the precise convergence in the later phase. In order to solve this problem, we have introduced self-adaptive step size with the specific behaviour description as follows.

Set X_i(t) as the current status of the artificial fish, then Y_i(t) is the function value of the current status X_i(t); set X_i(t+1) as the next status of the artificial fish and X_v(t) is the next status searched by the artificial, then Y_v(t) is the function value with the formula as follows:

$$X_v(\mathrm{t}) = X_i(\mathrm{t}) + Visual \bullet Rand(), \tag{7}$$

$$X_i(\mathrm{t+1}) = X_i(\mathrm{t}) + \frac{X_v(\mathrm{t}) - X_i(\mathrm{t})}{\| X_v(\mathrm{t}) - X_i(\mathrm{t}) \|} \bullet \left| 1 - \frac{Y_v(\mathrm{t})}{Y_i(\mathrm{t})} \right| \bullet Step \ (\text{Minimization problem}). \tag{8}$$

From the above formula, it can be seen that the movable step size in the algorithm is determined by the current status and the sensing status within horizon.

4 The noisy image threshold segmentation based on afsa

The main idea of the noisy image segmentation method based on AFSA is: consider the threshold of the noisy image as the individual fish in the fish swarm; the threshold distribution range $[a,b]$ is the feeding space of the fish swarm and find the optimal segmentation threshold through the chemotaxis, reproduction and elimination-dispersal with Formula 1 as the behaviour guide of fish feeding, namely the fitness function of AFSA.

The main steps are:

(1) Read in the image to be segmented;

(2) Decompose the image to be segmented with three-level sym5 wavelet and proceed wavelet reconstruction by the decomposed 3rd-level low-frequency and high-frequency coefficients to obtain the noise-suppressing enhanced image;

(3) Determine the threshold distribution range based on the histogram of the enhanced image;

(4) Get the fitness function of AFSA through Formula (1) by using the two-dimensional histogram of the enhanced image and its neighbourhood mean-value image;

(5) Set the control parameters in AFSA;

(6) Calculate the fitness of every individual fish and record the fish with the biggest fitness as well as its fitness;

(7) Chemotaxis operation: firstly, the fish overturns according to the following formula:

$$P(i, j+1, k, l) = P(i, j, k, l) + C(i) \times \Delta(i). \tag{9}$$

In this formula, $P(i, j, k, l)$ is the position of i-th fish in the l-th elimination-dispersal, the k-th reproduction and the j-th chemo taxis; $P(i, j+1, k, l)$ is the overturn new position of the i-th fish in the l-th elimination-dispersal, the k-th reproduction and the j-th chemotaxis; $C(i)$ is the step size of the i-th fish and $\Delta(i)$ is a random vector among [-1,1];

Then, compare whether the fitness of the fish after the overturn has been improved. If the fitness is improved, then the fish moves forward according to the below formula:

$$P(i, j+1, k, l) = P(i, j, k, l) + C(i) \times \Delta(i). \tag{10}$$

Otherwise, add 1 to the number of chemotaxis j; when $j < N_c$, the fish repeats the chemotaxis operation in this step. If not, the fish turns to Step (8).

Finally, compare the fitness after the fish moves forward and the biggest fitness recorded in this bulletin board to make the biggest fitness and the corresponding position are always kept in the board;

(8) Reproduction operation: calculate the fitness cumulative sum in the chemotaxis:

$$SumFitness(i) = \sum_{j=1}^{Nc+1} Fitness(i, j, k, l) . \quad (11)$$

Rank the fitness accumulative sum of the fish in the descending order. Make the weak fish to get the position and step size of the optimal fish and add 1 to the number of reproduction k. If $k < N_{re}$, turn to Step (7); otherwise, turn to Step (9);

(9) Elimination-dispersal Operation: the fish is dispersed to any random position in the solution space with the possible P_{ed} and add 1 to the number of elimination-dispersal. If $l < N_{ed}$, implement Step (7); otherwise, turn to Step (10);

(10) Output the optimum in the bulletin board and end the entire feeding process;

(11) Obtain the segmented image according to the following formula:

$$bw(x, y) = \begin{cases} 0, \text{当} 0 \le f(x, y) + g(x, y) \le s + t \\ 1, \text{当} f(x, y) + g(x, y) > s + t \end{cases} . \quad (12)$$

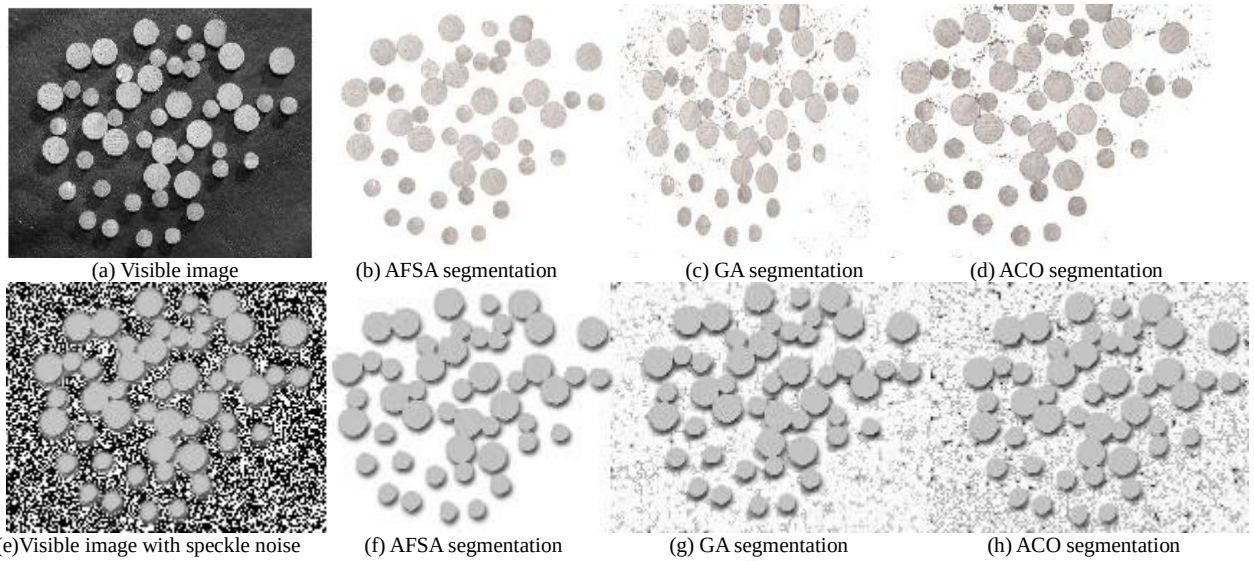
In this formula, $f(x, y)$ is the grey level of pixel (x, y); $g(x, y)$ is the average grey level of its 3×3 small neighbourhood pixel and $bw(x, y)$ is the grey value of pixel (x, y) after segmentation.

5 The experimental result and performance analysis

The following experiments are conducted in order to verify the effectiveness of the segmentation methods of AFSA.

5.1 THE COMPARISON OF SEGMENTATION EFFECTS

Segment the visible image and the visible image with speckle noise by using AFSA, genetic algorithm and ant colony optimization algorithm and the results are indicated as Fig.1. After conducting histogram analysis pre-processing on the images to be segmented, the threshold distribution range of Fig.1(a) is [103, 221] and that of Fig. 1(e) is [106, 218].



(a) Visible image (b) AFSA segmentation (c) GA segmentation (d) ACO segmentation

(e)Visible image with speckle noise (f) AFSA segmentation (g) GA segmentation (h) ACO segmentation

FIGURE 1 Image segmentation result comparison with different optimization algorithms

When using the segmentation method of AFSA, the segmentation result is clear-cut and intact with optimal performance.

5.2 THE COMPARISON OF SEGMENTATION SPEED

In order to test the segmentation speed of this method, the following table has presented the segmentation time and segmentation threshold by using AFSA segmentation methods, GA, ACO and PSO to segment Fig.1(a), as indicated as Table 1.

From Table 1, it can be seen that the segmentation time order of the above methods is: the method in this chapter<ACO<PSO<GA. The reason is that the new method adopted in this paper, on one hand, can reduce the search range of the threshold by conducting histogram pre-processing on the image to be segmented and on the other hand, quickly find the optimal threshold of the image to be segmented by introducing the parallel search mechanism of AFSA.

TABLE 1 The results by using different segmentation methods to segment fig.1

Optimization Algorithm	Fitness Function	Threshold	Run Time/S
AFSA	Two-Dimensional Maximum Between-Cluster Variance	68	5.047
GA	Two-Dimensional Conditional Entropy	131	8.372
ACO	Two-Dimensional OTSU	63	6.846
PSO	Improved Two-Dimensional Grey Entropy	153	7.478

6 Conclusion

This paper has proposed an improved AFSA image threshold segmentation method. Use histogram analysis techniques; design the trace of two-dimensional histogram scatter matrix of OTSU as the fitness function and instruct the search direction of the fish swarm in AFSA. Then, narrow down the threshold distribution range by enhancing the histogram information of the enhanced image and reduce the search range of the fish swarm in AFSA. Finally, with AFSA as the parallel threshold search strategy, accelerate the segmentation process and find the optimal threshold of the image to be segmented. The experimental results demonstrate the effectiveness of the new method, which can search the optimal threshold quickly and exactly.

A modified BFGS method and its convergence

Ganzhou Wu*, Haiyan Liang

School of Science, Guangdong University of Petrochemical Technology, Maoming 525000, Guangdong, China

Received 1 July 2014, www.cmnt.lv

Abstract

In this paper, a new modified BFGS method for unconstrained optimization problems is presented. The algorithm preserves the convergence properties of the famous BFGS algorithm. The relation between the new algorithm and a self-scaling quasi-Newton algorithm is revealed. If we assume the objective function is twice continuously differentiable and uniformly convex, we prove the iteration converge globally to the solution. And under some additional conditions, the superlinear convergence is given. Finally, the experimental results show that the proposed algorithm performs very well, which indicate that the numerical performance of the new algorithm is somewhat like the self-scaling quasi-Newton algorithm.

Keywords: modified BFGS method, convergence, unconstrained problems

1 Introduction

In this paper, we consider the following unconstrained optimization problems. See Equation (1).

$$\min f(x), x \in \mathbf{R}^n, \tag{1}$$

where $f: R^n \to R$ is continuously differentiable. The BFGS method is a well-known quasi-Newton method for solving unconstrained problems. During the past two decades, the study on global convergence of the quasi-Newton method has received growing interests. When f is convex, it was shown that Broyden's class of quasi-Newton methods converge globally if exact line search is used [1].When inexact line search is used, Powell [2] first obtained the global convergence of BFGS method. Byrd, Nocedal and Yuan [3] extended Powell's results to the restricted Broyden's class of quasi-Newton methods with Wolfe-Type line search except for DFP method. Yuan [4] and Wei [5] proposed modified secant equations which approximate the curvature of the objective function more accurate than the standard secant equation. On the other hand, in order to solve the nonconvex problems, Li and Fukushima [6] made a slight modification to the standard BFGS method.

Recently, Lewis and Overton [7] have shown in numerical experiments that the standard BFGS method works very well when applied directly without modifications to nonsmooth test problems as long as a weak Wolfe line search is used. All the mentioned methods in [3, 4, 5, 6] use both the gradient and function values available at the current iteration. In the cases that the Hessian matrix has some special structures and is partially available. For example, in the nonlinear least squares problems, the above mentioned secant equations have been developed by Amini and Ghorbani Rizi [8]. Xiao [9] proposed a modified limited memory BFGS method for solving the unconstrained. Saman [10] proposed two effective hybrid conjugate gradient algorithms based on modified BFGS updates. In the paper, we will analysis how to form the approximate matrix and how to use the formed approximate matrix to replace the inverse of the Hessian matrix in the BFGS method. Compared to the traditional BFGS method, the modified BFGS is also well-defined.

BFGS requires only matrix-vector multiplications which brings the computational cost at each iteration from $O(n^3)$ for Newton's method down to $O(n^2)$. However, if the number of variables is very large, even $O(n^2)$ per iteration is too expensive - both in terms of CPU time and sometimes also in terms of memory usage (a large matrix must be kept in memory at all times). According to the idea of Li and Fukushima. In the paper a modified BFGS method for unconstrained problems is applied even if the number of variables is very large. The modified BFGS method can save computing time.

The organization of this paper is as follows. In the next section we shall describe the new modified BFGS algorithm. If we assume the objective function is twice continuously differentiable and uniformly convex, according to the idea of Byrd, in section 3 we prove the iteration converge globally to the solution, and in section 4 under some additional conditions we show the method is superlinearly convergent. In section 5 the numerical results of the algorithm is shown. Finally, we make conclusions in section 6.

2 The new modified BFGS method

For brevity, we first introduce some notations used in this paper: $g_k = g(x_k), g = \nabla f$ gradient of f ; $G = \nabla^2 f$

* ***Corresponding author*** e-mail 330387742@qq.com

Hessian matrix of f ; d_k, λ_k, search vector/step length; $s_k = x_k - x_{k-1}, y_k = g_k - g_{k-1}$.

With $\|.\|$ we will denote the Euclidean vector norm in R^n, as well as the corresponding operator norm of matrices in $\mathbf{R}^{n\times n}$.

Algorithm 2.1(the new modified BFGS method)

Step1: Choose an initial point $x_1 \in \mathbf{R}^n$ and an initial positive definite matrix $\mathbf{B}_1$, and positive constants α, β with $0 < \alpha < 0.5, \alpha < \beta < 1$. Let $k = 0$.

Step2: If $g_k = 0$, stop; otherwise, go to Step3.

Step3: For given $x_k, \mathbf{B}_k$, solve the system of linear equation $\mathbf{B}_k d_k + g_k = 0$ to obtain a unique optimal solution d_k.

Step4: Compute λ_k, which satisfies

$$\mathbf{B}_{k+1} = \mathbf{B}_k - \frac{\mathbf{B}_k s_k s_k^{\mathrm{T}} \mathbf{B}_k}{s_k^{\mathrm{T}} \mathbf{B}_k s_k} + \frac{y_k y_k^{\mathrm{T}}}{y_k^{\mathrm{T}} s_k}, \tag{4}$$

where $y_k = \begin{cases} \bar{y}_k \\ \bar{y}_k + (c\|g_k\| - \dfrac{\bar{y}_k s_k}{\|s_k\|^2}) \end{cases}$,

$$\text{if} \quad y_k^{\mathrm{T}} s_k \geq c\|g_k\|\|s_k\|^2, \tag{5}$$

else

$$\bar{y}_k = g_{k+1} - g_k + r_k s_k, \tag{6}$$

and

$$r_k = \frac{3(g_{k+1} + g_k)^{\mathrm{T}} s_k - 6(f_{k+1} - f_k)}{\|s_k\|^2} \tag{7}$$

then set $k = k+1$, go to Step2.

3 Global convergence

In this section, we study the global convergence of algorithm2.1.First we make the following assumptions:
(1): The level set $D = \{x \mid f(x) \leq f(x_0)\}$ is contained in a bounded convex set D.
(2): The objective function f is continuously differentiable on D and there is a constant $L > 0$ such that for any $x, y \in D$,

$$\|g(x) - g(y)\| \leq L\|x - y\|. \tag{8}$$

(3): The function f is uniformly convex, i.e., there exist two positive constants m and M such that

$$m\|z\|^2 \leq z^{\mathrm{T}} G(x) z \leq M\|z\|^2 \tag{9}$$

for all $z \in \mathbf{R}^n$ and all $x \in D$.

Lemma 3.1 Suppose the sequence $\{x_k\}$ is generated by Alorithm 2.1.Then we have for every $k = 0,1,\cdots$, $f(x_{k+1}) - f(x_k) < 0$.

Proof: For any positive definite matrix $\mathbf{B}_{k-1}$, from (2) we get $f(x_{k+1}) - f(x_k) \leq \alpha\lambda_k g_k^{\mathrm{T}} d_k = -\alpha\lambda_k d_k^{\mathrm{T}} \mathbf{B}_{j-1} d_k < 0$, it implies that the new iteration point belongs to D. Due to (3) we also have

$$y_k^{\mathrm{T}} d_{k-1} = (g_k - g_{k-1}) d_{k-1} \geq -(\beta - 1) d_{k-1}^{\mathrm{T}} \mathbf{B}_{j-1} d_{k-1} > 0. \tag{10}$$

Since $s_k = \lambda_{k-1} d_{k-1}$, from (10) we get $y_k^{\mathrm{T}} s_k > 0$, this indicates that Alorithm 2.1 has the property if $\mathbf{B}_{k-1}$ is symmetric positive definite, then $\mathbf{B}_k$ is also symmetric positive definite.

Lemma 3.2 Let the sequence $\{x_k\}$ is generated by Alorithm 2.1.Suppose the assumption hold. Then we can get

$$\|y_k\| \leq \max\{7L, 7L + cC_1\}\|s_k\|, k = 1, 2, \ldots. \tag{11}$$

Proof: By using (5), if $\bar{y}_k^{\mathrm{T}} s_k \geq c\|g_k\|\|s_k\|^2$, we have $y_k = \bar{y}_k$. Therefore, $\|y_k\| \leq \|g_{k+1} - g_k\| + |r_k|\|s_k\|$, from the (8), we have

$$y_k \leq (L + |r_k|)\|s_k\|, \tag{12}$$

where $|r_k| = \dfrac{|3(g_{k+1} - g_k)^{\mathrm{T}} s_k - 6(f_{k+1} - f_k)|}{\|s_k\|^2}$.

From the Taylor's formula, we get

$$|r_k| \leq \frac{|3(g_k + \theta_1 s_k) - g_{k+1} + 3(g_k + \theta_1 s_k) - g_k|}{\|s_k\|^2} \leq 6L. \tag{13}$$

Substitute (13) into (12), we can get $\|y_k\| \leq 7L\|s_k\|, k = 1, 2, \ldots$.

In the other hand, if $y_k = g_{k+1} - g_k + r_k + c\|g_k\| - \dfrac{\bar{y}_k^{\mathrm{T}} s_k}{\|s_k\|^2} s_k$, using the Taylor's formula and (8), we also get

$$\|y_k\| \leq \|g_{k+1} - g_k\| + |r_k| + c(\|g_k\| + \frac{\|\bar{y}_k^{\mathrm{T}} s_k\|}{\|s_k\|^2})\|s_k\|$$

$$\leq (7L + c\|g_k\|)\|s_k\|.$$

According to the assumption (1), there exists a positive constant C_1, $\|g_k\| \leq C_1$, thus, we have $\|y_k\| \leq (7L + cC_1)\|s_k\|$.

According to the assumption (1), there exists a positive constant C_1, $\|g_k\| \leq C_1$, thus, we have $\|y_k\| \leq (7L + cC_1)\|s_k\|$.

Lemma 3.3 Let the sequence $\{x_k\}$ is generated by Alorithm 2.1. Suppose $\mathbf{B}_0$ is symmetric positive definite.

Then there is a constant $H \geq 0$ for all $k \geq 1$, y_k and s_k satisfy

$$\frac{\|y_k\|^2}{y_k^{\mathrm{T}} s_k} \leq H, \tag{14}$$

Consequently, for any $p \in (0,1)$ there exist positive constants $\beta_1, \beta_2, \beta_3$ such that, for $k \geq 1$ the following inequality

$$\beta_2 \leq \frac{\|\mathbf{B}_j s_j\|}{\|s_j\|} \leq \frac{\beta_3}{\beta_1} \equiv \beta. \tag{15}$$

Proof: Using Lemma 3.2, we can easily get $\frac{\|y_k\|^2}{y_k^{\mathrm{T}} s_k} \leq \frac{\max\{7L, 7L + cC_1\}\|s_k\|}{\|s_k\|}$.

Therefore, we have $\frac{\|y_k\|^2}{y_k^{\mathrm{T}} s_k} \leq H$, where $H = \max\{7L, 7L + cC_1\}$. From the theorem 2.1 in [11], we get (15).

Our proof is completed.

We defined set $K = \{k \mid k \text{ satisfies (15)}\}$.

Thus, from the right hand of (15), we have

$$\|\mathbf{B}_k s_k\| \leq \beta \|s_k\|, \quad k \in K. \tag{16}$$

Moreover, for all $k \in K$, $\|\mathbf{B}_k s_k\| = |\lambda_k| \|\mathbf{B}_k d_k\| = |\lambda_k| \|g_k\| \leq \beta \|s_k\| = \beta |\lambda_k| \|d_k\|$.

So we can get

$$\|g_k\| \leq \beta \|d_k\|. \tag{17}$$

By using $y_k = \mathbf{B}_k s_k$ and (9), we have

$$m\|s_k\|^2 \leq \left\|s_k^{\mathrm{T}} \mathbf{B}_k s_k\right\| \leq M\|s_k\|^2, \tag{18}$$

where m and M are positive constants.

There m 3.4 Let the sequence $\{x_k\}$ is generated by Alorithm 2.1.Suppose the assumption hold. Then we get

$$\liminf_{k \to \infty} \|g_k\| = 0. \tag{19}$$

Proof: We firstly assume $\|g_k\| \geq \varepsilon$ for all $k \in K$ with positive constant ε. Using Lemma 3.1, (16), (18) and $\mathbf{B}_k s_k = \lambda_k \mathbf{B}_k d_k = -\lambda_k g_k$, we can get

$$+\infty \geq \sum_{k=0}^{\infty} (-g_k^{\mathrm{T}} s_k) = \sum_{k=0}^{\infty} \frac{1}{\lambda_k} s_k^{\mathrm{T}} \mathbf{B}_k s_k = \sum_{k=0}^{\infty} \lambda_k \frac{\|g_k\|^2}{\|\mathbf{B}_k s_k\|^2} s_k^{\mathrm{T}} \mathbf{B}_k s_k$$
$$\geq \sum_{k=0}^{\infty} \frac{\|g_k\|^2}{\|\mathbf{B}_k s_k\|^2} s_k^{\mathrm{T}} m \|s_k\|^2 \geq \sum_{k=0}^{\infty} \beta^{-2} m \|g_k\|^2 \geq \sum_{k=0}^{\infty} \beta^{-2} m \varepsilon^2 = \infty.$$

It is obvious that we have derived a contradiction, so (19) holds.

The above theorem is established the global convergence of Alorithm 2.1.

4 Superlinear convergence

In order to give the superlinear convergence of Algorithm 2.1, we also need the following assumptions. Let x^* be the limit of the sequence $\{x_k\}$.

(4): f is twice continuously differentiable for all x in the neighbourhood of x^*.

(5): $\{x_k\}$ converges to x^*, where $g(x^*) = 0$ and $G(x^*)$ is positive definite.

(6): There exist two constants $M_2 \geq 0$ and $v \geq 0$ such that

$$\left\|G(x) - G(x^*)\right\| \leq M_2 \left\|x - x^*\right\|^v. \tag{20}$$

Lemma 4.1 Suppose assumptions (4)-(6) hold. Let us define θ_k as the angle between s_k and $\mathbf{B}_k s_k$. According to Byrd [3], it follows that $\cos\theta_k = \frac{s_k^{\mathrm{T}} \mathbf{B}_k s_k}{\|s_k\| \|\mathbf{B}_k s_k\|}$, so we get

$$a_1 \|g_k\| \cos\theta_k \leq \|s_k\|, \tag{21}$$

where a_1 is a positive constant.

Proof: From the assumption (2) and the definition y_k, we obtain

$$y_k s_k^{\mathrm{T}} \geq c\|g_k\|\|s_k\|^2 \geq c\|s_k\|(-g_k^{\mathrm{T}} s_k) \geq c\varepsilon_0(-g_k^{\mathrm{T}} s_k). \tag{22}$$

Combining assumption (4) and assumption (2), we have $\|G(x)\| \leq M_1$, $\|g(x)\| \leq M_2$, with M_1 and M_2 are a positive constants.

So we get

$$M_1 \|s_k\|^2 \geq \|G(\varepsilon_1) s_k\| \|s_k\| = \|g_{k+1} - g_k\| \|s_k\| \geq y_k s_k^{\mathrm{T}}$$
$$\geq c\varepsilon_0(-g_k^{\mathrm{T}} s_k) = c\varepsilon_0 \|g_k\| \|s_k\| \cos\theta_k, \tag{23}$$

where $\varepsilon_1 = x_k + \delta s_k, \delta \in (0,1)$.

(23) implies (22) holds, where $a_1 = \frac{c\varepsilon_0}{M}$.

Lemma 4.2 If the assumptions (1)-(6) hold, for an arbitrary $v > 0$, we can obtain

$$\sum_{k=0}^{\infty} \left\|x_{k+1} - x_k\right\|^v < +\infty, \tag{24}$$

and

$$\sum_{k=0}^{\infty} r_k < +\infty, \tag{25}$$

where $r_k = \max\{\left\|x_{k+1} - x^*\right\|^v, \left\|x_k - x^*\right\|^v\}$.

Proof: By the assumption (4) and (5), we have the following inequality

$$\|g(x)\| = \|g(x) - g(x^*)\| \geq m_1 \|x - x^*\|, \quad (26)$$

where m_1 is a positive constant.

From (15) and Lemma 4.1, we have

$$\cos\theta_k \geq 1/\beta. \quad (27)$$

Therefore,

$$\begin{aligned} -g_k^{\mathrm{T}} s_k &= \|g_k\|\|s_k\|\cos\theta_k \geq a_1 \|g_k\|\cos^2\theta_k \\ &\geq a_1 m_1^2 \|x_k - x^*\|\cos^2\theta_k \\ &\geq a_1 m^2 \frac{1}{\beta}\|x_k - x^*\|^2 \end{aligned} \quad . \quad (28)$$

By (2), (3) and (28), we can get (24).It is obvious that (25) hold.

Theorem 4.3 Let $\{\mathbf{B}_k\}$ and $\{x_k\}$ be generated by Alorithm 2.1, f satisfies assumption (4)-(6), then for any $k \geq 0$, we can get

$$(1):\ \lim_{k\to\infty} \frac{\|(\mathbf{B}_k - G(x^*))s_k\|}{\|s_k\|} = 0, \quad (29)$$

(2): $\{x_k\}$ generated by Alorithm 2.1 superlinearly converges to x^*.

Proof: By using Lemma 4.1 and Lemma 4.2, we can easily obtain (29).Similar to the arguments of Dennis [11], we get

$$\lim_{k\to\infty} \frac{\|x_{k+1} - x^*\|}{\|x_k - x^*\|} = 0. \quad (30)$$

5 Numerical experiments

In this section we present the results of our numerical experiments to compare the algorithm suppose by Broyden in [1] and the algorithm 2.1 in this paper. For brevity, we use BFGS and MBFGS to represent the algorithm suppose by Broyden in [1] and the algorithm 2.1 in this paper. All the numerical experiments will be programmed by matlab2012b. Let us choose the same starting point for both BFGS and MBFGS. In algorithm 2.1, while $c = 10^{-3}$, $\alpha = 0.3, \beta = 0.8$, $\mathbf{B}_0 = E$, and the experiment is stop when $\|g\| \leq 10^{-5}$.

(i) Problem 1. $f(x) = x_1^4 + x_2^4 + 2x_1^2x_2^2 - 4x_1 + 3$,

(ii) Problem 2. $f(x) = (x_1 + x_2)^2 + [2(x_1^2 + x_2^2 - 1) - \frac{1}{3}]^2$,

(iii). Problem 3. (Rosenbrook's function, $n = 2$) $f(x) = 100(x_2 - x_1^2)^2 + (1 - x_1)^2$

(iv). Problem 4 (Cube function, $n = 2$) $f(x) = 100(x_2 - x_1^3)^2 + (1 - x_1)^2$

Please see Table 1.

TABLE 1 Numerical results of BFGS and MBFGS methods

Test Functions	Initial points	n_i		n_f		x^*	f^*
		BFGS	MBFGS	BFGS	MBFGS		
	(1.25,1.25)	8	5	41	26		
(i)	(12,12)	8	6	41	31	(1,0)	0
	(45,45)	8	6	41	31		
	(-1.25,0.5)	8	6	41	31		
(ii)	(-1.25,-1)	13	9	62	42	(0.763756, 0.763679)	0
	(-1.25,1)	7	5	35	26		
	(-10,10)	30	12	151	61		
(iii)	(10,-10)	68	23	341	156	(1,1)	0
	(100,100)	167	25	836	235		
	(10,10)	52	18	46	31		
(iv)	(30,80)	75	23	61	42	(1,1)	0
	(-15,15)	28	19	72	32		

In Table 1, n_i and n_f indicates the number of iteration and the number of function evaluation respectively. Meanwhile, *x** and *f** indicates minimum points and minimum value respectively. It can be seen from the comparison given above that the algorithm 2.1 in this paper is more efficient than BFGS method for solving unconstrained optimization.

6 Conclusions

In this paper, a modified BFGS algorithm for unconstrained problems is proposed. If we assume the objective function is twice continuously differentiable and uniformly convex, we prove the iteration converge globally to the solution. And under some additional conditions the superlinear convergence is given. The method retains the scale-invariance property of the original BFGS method. We have preliminary numerical results to show its efficiency. As demonstrated in Section 5, the reported numerical results show that the modified BFGS performs better than the BFGS in [1].

Abstract

In order to solve the Blind Speed Side Lobe (BSSL) appeared in Radon-Fourier Transform (RFT) method used for dim target detection, a novel method of BSSL suppression is proposed in this paper. It is based on Random Pulse Repetition Interval (RPRI). The process of RPRI-RFT and the BSSL properties are described, the performance of coherent integration and the modulation noise of RFT algorithm based on RPRI are analysed in detail. Both the theoretical analysis and the numerical experimental results show that RPRI-RFT can be used to improve signal-to-noise ratio (SNR) and suppress BSSL effectively, and the influence of modulation noise of RPRI can be suppressed by the long-time integration characteristic, thus significantly improve the ability of low pulse repetition frequency radar to detect and measure long-range weak high-speed multi-targets.

Keywords: Blind Velocity Side Lobe, Radon-Fourier Transform, Random Pulse Repetition Interval

1 Introduction

With the development of radar stealth technology, the radar cross section (RCS) of target decreases sharply, weakening the energy of radar echo and diminishing the range of radar detection. Long-time integration is an effective method to improve the detection performance of dim targets [1-3]. With the increase of integration time, however, the problem of across range unit (ARU) walk will occur inevitably. Performing directly conventional methods of moving target detection (MTD) on high-velocity targets, the energy of targets spread over multiple resolution units [4-6] and cannot be integrated effectively. In this case, the increase of integration time cannot improve the performance of radar detection.

Non-coherent integration and coherent integration are two basic methods for long-time integration. The former mainly accumulates the energy along with the motion trajectory of targets to solve the problem of ARU. As a typical algorithm, the Hough Transform (HT) proposed by Carlson does not need phase compensation, making it easy to implement [7-9]. However, without phase information, the energy of target cannot be accumulated completely and this method cannot work well in extremely low SNR scenario [10]. The latter has drawn extensive attention from academic community and has been deeply investigated in recently years, because of its better integrated gain in the field of dim target detection. Techniques for ARU compensation in the long-time coherent integration can be classified into two types. In the first type, ARU compensation can be implemented by shifting or expanding the envelope after pulse compression [11]. In order to guarantee the compensation precision, interpolation in range dimension should be adopted, so the memory cost is huge. In the second type, ARU compensation is realized in the transform domain of the range-pulse plane, such as Keystone transformation, achieving ARU compensation of constant-velocity targets [12-14]. This method is free of searching operation, but it cannot eliminate the ARU effect for multiple targets with different ambiguity number simultaneously.

In recent years, based on the coupling relationship between range walk and Doppler frequency, Radon-Fourier Transform (RFT) is proposed to realize the long-time coherent integration [15-17] by mapping the echo pulse to the range-Doppler plane. RFT concentrating the energy to a focused peak, improves the radar detection performance of dim targets. However, because of the discrete pulse sampling, finite range resolution and limited integration time, the BSSL still exists in the case of Low Pulse Repetition Frequency (LPRF). Since the BSSL would increase the ratio of false alarm and deteriorate the detection performance, a symmetrical weighting method has been proposed to suppress the BSSL in RFT integration plane. The locations of BSSLs can be controlled via different weighting functions, and the BSSLs can be eliminated by combing the different weighted RFT results [16]. However, BSSLs still cannot be eliminated completely when the BSSLs appear simultaneously in both RFT outputs. Another method based on the design of pulse repetition interval (PRI) has been proposed in Ref. [18]. By jointly processing the RFT outputs in two adjacent Coherent Processing Intervals (CPIs), minimum criterion is employed between

* ***Corresponding author*** e-mail 3241126@qq.com

the two different PRI to achieve BSSL suppression. It should be note that the algorithm needs at least two CPIs, so that the integration time is increased twice and the radar efficiency is halved. A BSSL suppression method based on CLEAN algorithm has been proposed in [19]. The peak position of echo envelope is first obtained after RFT operation, and according to the relationship among BSSL, velocity and range, the positions of BSSL are confirmed and removed. And then the RFT peak will be determined. Though the BSSL of one target can be well restrained, the target cannot be detected when its main lobe overlaps the BSSL of another target.

In this paper, a novel RFT algorithm based on Random Pulse Repetition Interval (RPRI) is proposed to suppress BSSL. And the paper is organized as follows: the principle of RFT algorithm is analysed, and the causes of BSSL of discrete RFT are presented in section 2. In section 3, the RFT algorithm based on RPRI is proposed, and the analyses about the modulation noise and BSSL suppression performance of RFT algorithm are presented. In section 4, the simulation results of the proposed method are shown. Finally, the conclusions are given out in section 5.

2 The characteristics of RFT

2.1 SIGNAL MODEL

Suppose a linear frequency modulation (LFM) signal $p(t)$ is used by the radar transmitting, i.e.,

$$p(t)=\mathrm{rect}\left(t/T_{\mathrm{P}}\right)\exp\left(\mathrm{j}\pi\gamma t^{2}\right), \tag{1}$$

where T_{p} is the pulse duration, γ is the modulation frequency rate, and $\mathrm{rect}(\bullet)$ is the rectangular function.

For a point target with the RCS of Swerlling-0 type, the received echo signal can be written as

$$s_{\mathrm{r}}(\hat{t},t_m)=A_{\mathrm{r}}\,p\left(\hat{t}-2r\left(t_m\right)/c\right)\exp\left(-\mathrm{j}4\pi f_{\mathrm{c}}\,r\left(t_m\right)/c\right), \tag{2}$$

where $\hat{t}$ and t_m ($t_m=mT_{\mathrm{r}}$, T_{r} is the PRI) denote the quick-time and slow-time respectively, f_{c} is the carrier frequency, c represents the light velocity and A_{r} is the amplitude of target. It is supposed that the radial velocity of the target is uniform. The instantaneous distance between radar and target can be expressed as $r\left(t_m\right)=r_0+v_0t_m$ where r_0 is the initial distance from radar platform to target, and v_0 is the radial velocity of target.

After range compression, the echo signal can be represented as

$$\begin{aligned}s_{\mathrm{r,M}}(\hat{t},t_m)=&A_0\mathrm{sinc}\left(B\left(\hat{t}-2\left(r_0+v_0t_m\right)/c\right)\right)\bullet\\&\exp\left(-\mathrm{j}4\pi f_{\mathrm{c}}\,r_0/c\right)\exp\left(-\mathrm{j}4\pi f_{\mathrm{c}}\,v_0t_m/c\right)\end{aligned}, \tag{3}$$

where A_0 is the amplitude of baseband signal, B is the bandwidth of LFM signal.

For the conventional MTD method，echo envelop is supposed to be in the same range unit, and the coherent integration results can be written as

$$S_{\mathrm{P}}(t,v)=\int_{T_{CPI}}s_{\mathrm{r,M}}\left(\hat{t},t_m\right)\exp\left(\mathrm{j}4\pi vt_m/\lambda\right)\mathrm{d}t_m, \tag{4}$$

where λ is the wavelength, $S_{\mathrm{P}}\left(t,v\right)$ is the coherent integration result in the range-velocity plane.

In equation (4), the pulse integration time should satisfy

$$T_{\mathrm{CPI}}\le\frac{\rho_{\mathrm{r}}}{v_{\max}}, \tag{5}$$

where ρ_r is the range resolution, and $\rho_{\mathrm{r}}=c/\left(2B\right)$.

However, in general cases, the maneuvering targets cannot satisfy (5) during the long integration time, so ARU will appear, thus affecting the coherent integration of energy. RFT algorithm is a solution way to deal with the effect of ARU. For uniform velocity motion, it can be expressed as

$$G\left(r,v\right)=\int s_{\mathrm{r,M}}\left(\frac{2\left(r+vt_m\right)}{c},t_m\right)\exp\left(\mathrm{j}\frac{4\pi vt_m}{\lambda}\right)\mathrm{d}t_m, \tag{6}$$

Equation (6) shows that the echo envelope of each slow-time is extracted along with the motion track $r\left(t_m\right)=r_0+v_0t_m$, and the phase terms are compensated based on the relationship between velocity and Doppler frequency. In contrast, equation (4) shows that the sample points are extracted in the same range cell for different pulse repetition interval. Therefore, RFT can integrate the energy of target completely, while MTD cannot. Since motion track of the target is unknown before detection, two-dimensional joint searching of range and velocity is required in the RFT algorithm.

In practical application, the discrete form of (6) can be rewritten as

$$\begin{aligned}G_D\left(r,v\right)=&\sum_{m=0}^{M-1}s_{\mathrm{r,M}}\left(\mathrm{round}\left(\frac{r+vmT_r}{\rho_r}\right),m\right)\bullet\\&\exp\left(\mathrm{j}4\pi\,vmT_{\mathrm{r}}/\lambda\right)=\\&A_0\sum_{m=0}^{M-1}\mathrm{sinc}\left(2B\left((r\text{-}r_0)+mT_r\left(v-v_0\right)\right)/\mathrm{c}\right)\bullet\\&\exp\left(\mathrm{j}4\pi\left(v-v_0\right)mT_{\mathrm{r}}/\lambda\right)\end{aligned}, \tag{7}$$

where M is the number of integrated pulses. The maximum of integration peak can be found by searching in distance-velocity parameters' plane, and the peak value can be written as

$$G\left(r_0,v_0\right)=A_0M. \tag{8}$$

2.2 RFT BSSL CHARACTERISTICS

For LPRI Pulse Doppler (PD) radar, the accumulating gain of MTD method (shown in (4)) at ambiguous frequency point $f_{\mathrm{d}}+k/T_{\mathrm{r}}$, corresponding to the ambiguous velocity $v(k)=v_0+kv_{\mathrm{b}}$, where $v_{\mathrm{b}}=\lambda/2T_{\mathrm{r}}$ is the blind velocity, is the same with true Doppler frequency point, the true velocity cannot be ascertained. For RFT method from equation (7), although phase fluctuation of ambiguous velocity $v(k)$ can still be compensated completely, only some sampling units can be accumulated effectively according to the false motion track of ambiguous velocity $v(k)$, if they are in the same range unit with the real motion track $r(t_m)=r_0+v_0t_m$. The valid integration number L of accumulated pulses, which satisfies the above condition, can be represented as

$$L=\begin{cases}\mathrm{round}\left(\left|\rho_r/(v-v_0)T_r\right|\right) & v\neq v_0\\ M & v=v_0\end{cases}. \tag{9}$$

In this case, RFT results can be rewritten as

$$G\left(r_0,v(k)\right)=A_0L_k=\frac{2A_0\rho_{\mathrm{r}}}{k\lambda}. \tag{10}$$

Thus, for LPRI PD radar, one main accumulating peak and several BSSLs are generated in RFT output, and the Primary Lobe-to-Side Lobe Ratio (PSLR) is

$$I_k=20\lg\left(\frac{Mk\lambda}{2\rho_{\mathrm{r}}}\right). \tag{11}$$

For constant wavelength, BSSL is relevant with the ambiguity number k, the number of accumulated pulse M and the distance resolution ρ_{r}. RFT processing can suppress the effect of MTD method on velocity ambiguity, and the suppression ratio is I_k. But RFT still cannot resolve the velocity ambiguity completely. In the case of multiple targets, the phenomena of false alarms will still exist when BSSLs exceed the threshold.

3 BSSL Suppression of RFT based on RPRI

3.1 PROCESS OF RPRI-RFT

PD radar with RPRI resolves the problem of velocity ambiguity by adding random jitter to uniform PRI, and it shows good performance in anti-interception and anti-electronic-jamming.

In RPRI case, slow-time t_m is random, and it can be represented as

$$t_m=mT_{\mathrm{r}}+d_m=(m+\delta_m)T_{\mathrm{r}}, \tag{12}$$

where δ_m is a jitter of uniform distribution added to the average repetition interval T_{r}, which satisfies $-0.5\le\delta_m\le0.5$. Then the discrete expression of RPRI-RFT can be written as

$$G_D(r,v)=\sum_{m=0}^{M-1}s_{\mathrm{r,M}}\left(\mathrm{round}\left((r+vmT_{\mathrm{r}}+vd_m)/\Delta R\right),m\right)\cdot\exp\left(4\pi\mathrm{j}v(mT_{\mathrm{r}}+d_m)/\lambda\right). \tag{13}$$

Comparing (13) with (7), there are two differences between RPRI-RFT and RFT. First, the envelope delay of the former increases with the random jitter, which is related to d_m instead of increasing linearly with slow-time t_m. When $vd_m\ll\Delta R$, the envelope delay jitter caused by RPRI is much less than the range resolution, and the RPRI can be considered to have no influence on the sampling of envelope. In fact, the condition usually can be satisfied in reality. Secondly, the phase term of RPRI-RFT is not only related to Doppler modulation, but also including a random term $\exp(4\pi\mathrm{j}v_0d_m/\lambda)$, which introduces random noise component to the processing result of RFT. Therefore, RPRI-RFT is equivalent to Non-Uniform Discrete Fourier Transform (NUDFT) along the track of range migration. The Mean and variance of $G_D(r,v)$ are analysed as follows.

The Mean of RPRI-RFT is expressed as

$$\begin{aligned}&E\left(G_D(r,v)\right)=\\ &E\left(\sum_{m=0}^{M-1}s_{\mathrm{r,M}}\left(\mathrm{round}\left((r+vmT_{\mathrm{r}})/\rho_r\right),m\right)\cdot\exp\left(\mathrm{j}4\pi\frac{v(mT_{\mathrm{r}}+d_m)}{\lambda}\right)\right)=\\ &A_0E\left\{\sum_{m=0}^{M-1}\mathrm{sinc}\left(2B(r-r_0)+(mT_r+d_m)(v-v_0)/c\right)\cdot\exp\left(\mathrm{j}4\pi(v-v_0)(mT_{\mathrm{r}}+d_m)/\lambda\right)\right\}\approx\\ &A_0E\left\{\left(\sum_{m=0}^{M-1}\mathrm{rect}(r-r_0)+(mT_r+d_m)(v-v_0)/\rho_r\right)\cdot\exp\left(\mathrm{j}4\pi(v-v_0)(mT_{\mathrm{r}}+d_m)/\lambda\right)\right\}\approx\\ &A_0E\left\{\sum_{m=0}^{L-1}\exp\left(\mathrm{j}4\pi(v-v_0)(mT_{\mathrm{r}}+d_m)/\lambda\right)\right\}\triangleq\\ &A_0x(r,v)\end{aligned}. \tag{14}$$

In (14), the condition supported the final approximate equation is $vd_m\ll\rho_{\mathrm{r}}$, that is, the envelope jitter caused by RPRI is far less than the range resolution. As a result, $x(r,v)$ in equation (14) is written as

$$
\begin{aligned}
&x(r,v)= \\
&E\left(\sum_{m=0}^{L-1}\exp\left(\mathrm{j}4\pi(v-v_0)(mT_\mathrm{r}+d_m)/\lambda)\right)\right)= \\
&\sum_{m=0}^{L-1}\exp\left[\mathrm{j}4\pi\left(v-v_0\right)mT_\mathrm{r}/\lambda\right]\bullet \\
&\mathrm{E}\left\{\exp\left[\mathrm{j}4\pi\left(v-v_0\right)d_m/\lambda\right]\right\}=\mathrm{sinc}\left[4\left(v_0-v\right)\alpha T_\mathrm{r}/\lambda\right]\bullet \\
&\sum_{m=0}^{L-1}\exp\left[\mathrm{j}4\pi\left(v-v_0\right)mT_\mathrm{r}/\lambda\right]=\mathrm{sinc}\left[4\left(v_0-v\right)\alpha T_\mathrm{r}/\lambda_\mathrm{r}\right]\bullet \\
&\frac{L\,\mathrm{sinc}\left[2\left(v_0-v\right)LT_\mathrm{r}/\lambda\right]}{\mathrm{sinc}\left[2\left(v_0-v\right)T_\mathrm{r}/\lambda\right]}\exp\left[\mathrm{j}2\pi\left(v_0-v\right)\left(L-1\right)T_\mathrm{r}/\lambda\right]
\end{aligned}
\quad . (15)
$$

The variance of RPRI-RFT is expressed as

$$
\begin{aligned}
\mathrm{D}\left(G_D\left(r,v\right)\right)=\mathrm{D}\Bigg\{&\sum_{m=0}^{M-1}\mathrm{s}_{\mathrm{r,M}}\left(\mathrm{round}\left(\left(r+vmT_\mathrm{r}\right)/\Delta R\right),m\right)\bullet \\
&\exp\left(\mathrm{j}\frac{4\pi v\left(mT_\mathrm{r}+d_m\right)}{\lambda}\right)\Bigg\} \\
=LA_0^{\,2}&\mathrm{sinc}^2\left(2B(r-r_0)\right)\left\{1-\mathrm{sinc}^2\left(4\left(v_0-v\right)\alpha T_\mathrm{r}/\lambda\right)\right\}
\end{aligned}
\quad . (16)
$$

In (16), when $v=v_0$, $D\left(G_D\left(r_0,v_0\right)\right)=0$, the main integration peak of RPRI-RFT has no noise component. When $v\neq v_0$, $L=\mathrm{round}\left(\left|\rho_\mathrm{r}/\left(v-v_0\right)T_\mathrm{r}\right|\right)$, however, $\mathrm{D}\left(G_D\left(r,v\right)\right)$ becomes smaller with increasing the deviate degree of v from v_0 according to equation (9). From (15) and (16), it can be seen that both the mean and variance of $G_D\left(r,v\right)$ have no relationship with the number of integrated pulses M. Therefore, the advantage of RPRI-RFT is that the amplitude of main peak corresponding to target parameter $\left(r_0,v_0\right)$ increases with the same proportion as M, while the variance of modulation noise corresponding to other range-velocity parameter points decreases when v deviates from v_0. Although noise is introduced by random modulation, it is still restrained after RFT processing so that target can be detected in low SNR when M reaches a certain value.

3.2 BSSL PROPERTIES OF RPRI-RFT

For the case of $v=v_0$, $L=M$, $E\left(G_D\left(r_0,v_0\right)\right)=A_0M$ and $D\left(G_D\left(r_0,v_0\right)\right)=0$, the random modulation has no influence on the integration amplitude of RFT Primary lobe.

The BSSL of RPRI-RFT output is random, and its mean is written as

$$
E\left(G_D\left(r_0,v(k)\right)\right)=\frac{2A_0\rho_r}{k\lambda}\mathrm{sinc}(2\alpha k)\,. \qquad (17)
$$

Compared with (10), the improvement factor of BSSL for RPRI-RFT can be written as

$$
I_a=\mathrm{sinc}(2\alpha k)\,. \qquad (18)
$$

It can be seen from Equation (18) that, the improvement of BSSL suppression is related to the jitter α and ambiguity number k. Specifically when $\alpha=0.5$, the mean of BSSL is 0.

The noise variance introduced after RPRI –RFT is computed to be

$$
\mathrm{D}\left(G_D\left(r_0,v(k)\right)\right)=\frac{2\rho_\mathrm{r}A_0^{\,2}\left(1-\mathrm{sinc}^2(2\alpha k)\right)}{k\lambda}\,. \qquad (19)
$$

In this case, PSLR of RPRI-RFT can be rewritten as

$$
\bar{I}_k=10\lg\left(\frac{M^2}{\left(\frac{4\rho_\mathrm{r}^{\,2}}{k^2\lambda^2}-\frac{2\rho_\mathrm{r}}{k\lambda}\right)\mathrm{sinc}^2\left(2\alpha k\right)+\frac{2\rho_\mathrm{r}}{k\lambda}}\right). \qquad (20)
$$

Equation (20) shows that, PSLR of RPRI-RFT can increase with the increase of M or the jitter α, so the performance of PSLR can be improved effectively by M and α. Formula (19) also shows that BSSL variance will reduce when ambiguity k increases, and however, BSSL variance cannot be completely zero even if α =0.5. Therefore, in order to eliminate BSSL, parameters α and M should be chosen reasonably.

4 Numerical experiments

Numerical simulations are done to verify the above analysis. The parameters of targets and radar are as follows: the radar carrier frequency is 2.5 GHz; the signal bandwidth is 5MHz; the complex sampling frequency is 10MHz; the pulse duration is 10μs; and average repetition frequency is 1 kHz. Three targets are assumed, and their distance and velocity are T_1(96 km, 680 m/s), T_2(96 km, 620 m/s) and T_3(94 km, 680 m/s) respectively.

4.1 UNIFORM PRI PROCESSING

The range walk does not occur when M = 32. For uniform PRI, the result of MTD is shown in Figure 1. Velocity ambiguity has emerged on three targets so that the real velocity cannot be obtained correctly. In addition, MTD processing cannot distinguish T_1 from T_2 in the same distance and Doppler unit in Figure 1.

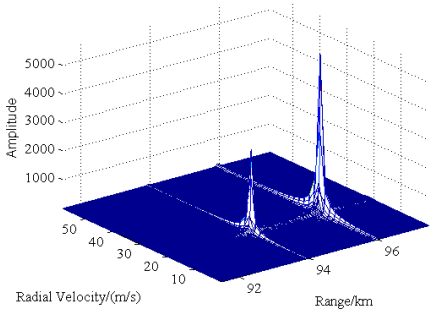

FIGURE 1 MTD results of uniform PRI when M=32

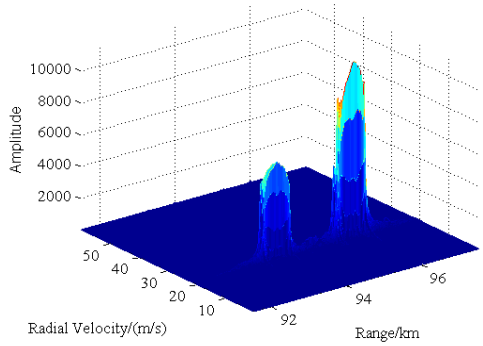
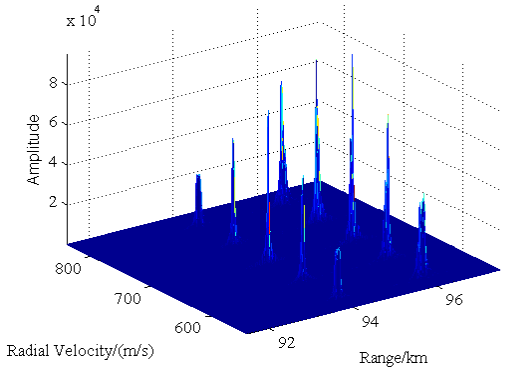
The ARU effect become much more evident when M =1024. The results of MTD and RFT are shown in Figure 2. Figure 2(a) shows that MTD processing cannot distinguish the three targets, because of ARU effect. Figure 2(b) shows that the targets cannot be distinguished because of BSSL, in this case, the PSLR is $I_k = 6.2\text{dB}$.



(a) MTD results



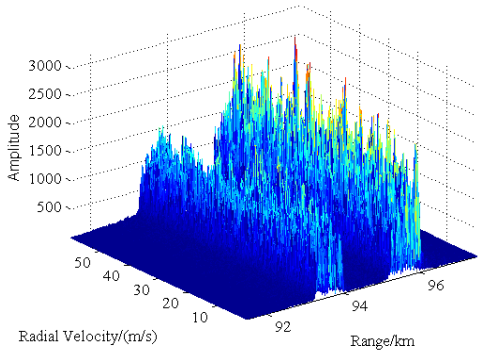
(b) RFT results

FIGURE 2 Results of uniform PRI when M =1024

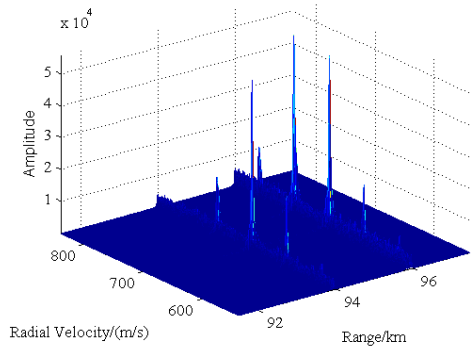
4.2 RESULT OF RPRI-RFT

On the basis of uniform PRI, RPRI status is presented, and the suppression of different jitters on blind side lobe is analysed, which is shown in Figure 3: (1) When $\alpha = 0.3$, MTD shown in Figure 3(a) is directly applied, and the velocity dimension accords with noise distribution; (2) When $\alpha = 0.3$, the RFT processing results are shown in Figure 3(b). The BSSL is further suppressed, and $\bar{I}_1$ =10.9dB, which is 4.7dB higher than Figure 2(b); (3) When $\alpha = 0.5$, the RFT processing results are shown in Figure 3(c). The BSSL of RFT is reduced sharply, and the PSLR is $\bar{I}_1$ =27.7dB.

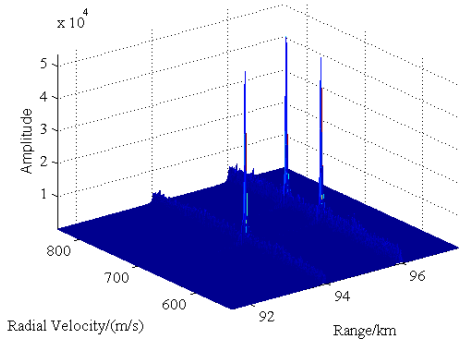
From the above simulation results, it can be observed that the noise does not affect distance resolution along the distance dimension, and the effect of modulation noise is small out of range resolution unit after RPRI-RFT processing; along the velocity dimension, the random modulation noise can be further suppressed, and the influence of modulation noise will be smaller when a certain pulse number M is selected.



(a) MTD results of $\alpha = 0.3$



(b) RPRI -RFT results of $\alpha = 0.3$



(c) RPRI-RFT results of $\alpha = 0.5$

FIGURE 3 Results of RPRI at M =1024

The following Figure 4 shows that PSLR values of different jitter α and the number of accumulated pulse M correspond to the position of the first side lobe.

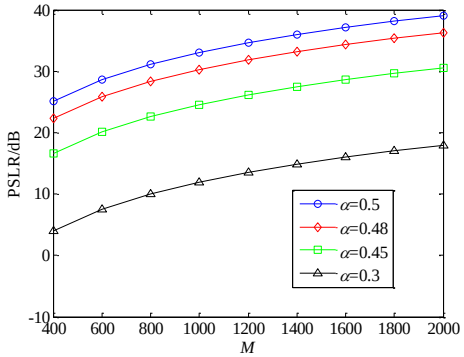


FIGURE 4 PSLR value of different α and M

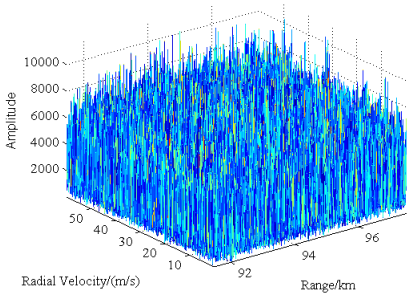
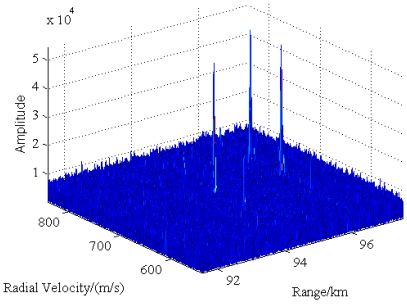
From Figure 4, it shows that the PSLR can be improved to 20 dB when M is more than 600 and $\alpha \geq 0.45$, and the PSLR can be improved to 30 dB when M is more than 1000 and $\alpha \geq 0.48$. These results show different ability to suppress of the BSLL at different parameters.

4.3 PERFORMANCE ANALYSIS OF RPRI-RFT IN LOW SNR

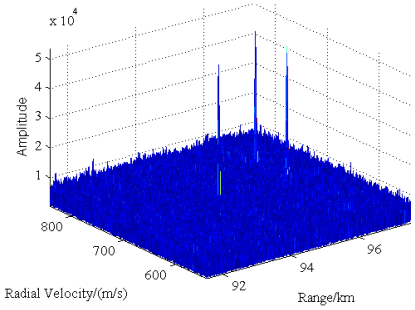
On the basis of section 4.2, Gaussian white noise is introduced, and the input SNR is -20dB. Experimental results are shown in Figure 5. Figure 5(a) shows that targets are submerged in noise after MTD processing. Figure 5(b) shows that signal energy can be integrated so that SNR can be improved substantially after RPRI-RFT processing. Figure 4(c) shows that after the increase of the PRI jitter, BSSL is submerged in noise, and the three pecks of the targets are all much higher than the noise background when the pulse number M is large enough (M =1024),in this case, the output SNR is 20.7dB.



(a) MTD results at $\alpha = 0.3$



(b) RPRI-RFT results at $\alpha = 0.3$



(c) RPRI- RFT results at $\alpha = 0.5$

FIGURE 5 Results of RPRI at M=1024 and SNR=-20dB

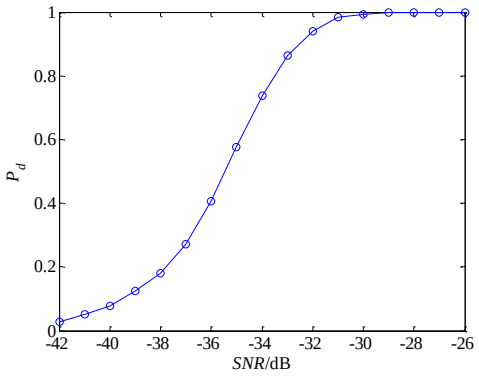


FIGURE 6 Detection performance at different input SNR

In order to analyse the detection performance at low input SNR, the results are given at different input SNR of 1000 Monte-Carlo simulation experiments in Figure 6. With detection probability P_d =80% and a given constant false alarm ratio P_f =10^{-6}, Figure 6 shows that the needed input SNR is -34.3dB at RPRI-RFT method.

Simulation results illustrate that RPRI-RFT can be well applied to resolve the problem of dim target detection and anti-velocity ambiguity, thereby achieving accurate velocity and distance of targets.

5 Conclusion

For the detection of the high-velocity dim target, the problem of ARU in long coherent integration time can be solved by RFT algorithm. However, BSSL of RFT algorithm may affect the detection when multiple targets exist in the observed scene. Therefore, a RFT algorithm with RPRI modulation has been proposed to restrain BSSL in this paper. The process of RPRI-RFT has been described and the BSSL properties of RPRI-RFT have been analysed in details. The experimental results have shown that RPRI-RFT can effectively restrain BSSL and the influence of modulation noise of RPRI can be suppressed by the characteristic of long-time integration of RFT. Therefore, the ability to detect long-range and high velocity dim targets has been improved effectively by RPRI-RFT, and proved by the simulation results.

Abstract

Ant colony algorithm (ACA) is a bionic intelligent optimization algorithm with positive feedback, distributed computing and heuristic search. As an important branch of computational intelligence and swarm intelligence, ACA has been successfully applied in solving many combinatorial optimization problems. Artificial neural network is a large-scale distributed parallel processing system with the characteristics of self-organization, self-study, self-adaptation and non-linear dynamic processing and it has a broad prospect in settling the complicated non-linear problems. This paper has proposed an algorithm used to solve multi-objective optimization problems and the applications of ACA.

Keywords: Ant Colony Algorithm; Neural Network

1 Introduction

Among the numerous swarm intelligence algorithms, the most remarkable is a self-organizational behaviour of the ant colony, namely that the ant can always find the shortest path between the ant nest and the food source in the foraging. Without visual capacity in finding the food, the ants can only find the path by releasing pheromone on the way. The ant individuals convey information through pheromone and choose the passing path according to the pheromone concentration. The higher pheromone concentration the path has, the higher probability the ants will choose this path. In this way, the process where the ants choose the path has formed a positive-feedback mechanism. The pheromone concentration of the optimal path increases gradually with time while those of the other paths decrease relatively and the ants will finally find the shortest path [1].

Dorigo M, an Italian scholar had first put forward a heuristic swarm intelligent bionic optimization algorithm, namely Ant Colony Algorithm (ACA) by simulating ant's behaviour in finding the shortest path. This algorithm has strong robustness, global convergence ability, distributed computing and feedback mechanism. In a short span of ten years, ACA has been extensively applied in a great number of optimization fields, including combinatorial optimization, network route, function optimization and robot path planning and it has been doing well especially in lots of discrete or continuous combinatorial optimization problems. At present, ACA has been used to settle a lot of practical problems such as Traveling Salesman Problem (TSP), the blind inspection problem of the signals, the assignment problem and Job Shop Scheduling Problem (JSSP) and it has achieved excellent effects [2].

ACA has a short period of development and there are still plenty of problems to be further researched and settled. It has been proved by the theoretical research and the practical applications in many fields that this algorithm has a bright development future. With the development of information technology and the advancement of human cognition, swarm intelligent bionic optimization algorithm will gradually become a useful tool of scientific knowledge; therefore, ant colony optimization algorithm and its applications will eventually be a long-term research focus and a forefront topic and it will arouse more attention from the public and have a broader development prospect [3].

2 Basic ant colony algorithm

Traveling Salesman Problem (TSP) is a typical combinatorial optimization problem and it is also the most successful example of ACA; therefore, ACA is always described with TSP as the application background. TSP can be described as follows: a traveling salesman needs to go back to the departure city after going through n cities only once apart from the starting city and TSP is supposed to find the shortest path among all the cities.

The ants in the natural world can always find the optimal path from the food to the cave or bypassing the obstacles when searching for food or encountering obstacles. The main reason is that the ants will release pheromone on the way and the subsequent ants can choose the next path to go according to the pheromone. The more pheromone a path has, the more times the path

* ***Corresponding author*** e-mail: ssss@dddd.com

is selected, the more excellent performance the path has and the higher probability the subsequent ants choose this path is; therefore, it forms a positive feedback of learning information and gets gradually closer to the optimal solution [4, 5].

TSP can be interpreted by the directed diagram G=(V,E), where V=(1,2…n) is the collection of the nods, E={(ij)} is the collection of the sides and D=(d_{ij}) is the Euclidean distance between i and j. Before using ACA to solve TSPs, it needs to restrict every artificial ant to only choose one city once along a path. After all the ants have searched a complete and legal path, update the corresponding pheromone to every side according to the paths the ants have gone through. In the searching process, the ant computes the probability according to the pheromone and the heuristic information in every path, based on which, the probability that the artificial ant moves from i city to j city at t in the next city is:

$$\rho_{ij}^{k}(t)=\begin{cases}\dfrac{[\tau_{ij}(t)]^{\alpha}[\eta_{ij}(t)]^{\beta}}{\sum_{s\in D_k}[\tau_{is}(t)]^{\alpha}[\eta_{is}(t)]^{\beta}}, j\in D_k\\ 0, \text{Others}\end{cases}. \quad (1)$$

In this formula, $D_k=\{0,1\cdots n-1\}-tabu_k$ is the city collection to be chosen when the artificial ant arrives at kth city. With a memory function, the artificial ant records the cities it has passed and makes dynamic adjustment with the evolution via $tabu_k(k=1,2,\cdots m)$. As time passes, the information left before disappears gradually. $\eta_{ij}(t)$ is the visibility of side ij and $\eta_{ij}=\dfrac{1}{d_{ij}}$; $\tau_{ij}(t)$ is the pheromone of ij at the time of t; d is the relative importance degree of the pheromone and 1-p is the volatization of pheromone. After some time, the ant finishes one cycle and adjusts the pheromones in every path cording to Formula (2) and (3).

$$\tau_{ij}(t+1)=\rho\tau_{ij}(t)+\Delta\tau_{ij}(t), \quad (2)$$

$$\Delta\tau_{ij}(t)=\sum_{k=1}^{m}\Delta\tau_{ij}^{k}(t). \quad (3)$$

In the above formula, $\Delta\tau_{ij}^{k}(t)$ is the pheromone left on ij by k ants in this cycle and $\Delta\tau_{ij}$ is the pheromone increment left on ij in this cycle.

$$\Delta\tau_{ij}^{k}\begin{cases}\dfrac{Q}{L_k}, \text{If kth ant pass through the ij in this loop}\\ 0, \text{Else}\end{cases}. \quad (4)$$

If the kth ant passes ij in this cycle, otherwise.

In Formula (1)-(4), the pheromone intensity Q is a constant and L_k is the total length of the path the kth ant takes in this loop.

At the initial moment, $\tau_{ij}(0)=C$, $\Delta\tau_{ij}=0$ $(i,j=0,1\ldots,n-1)$ [6, 7].

3 The applications of ant colony optimization algorithm in artificial neural network

3.1 ARTIFICIAL NEURAL NETWORK

Artificial Neural Networks (ANNs), also called Neural Networks (NNs), is a mathematical model by simulating Biological Neural Networks (BNNs) to conduct information processing. Based on the psychological research achievements of brain, it is aimed to simulate some mechanism of the brain and realize some specific functions. Currently, ANNs have been widely used in many fields.

The basic information processing unit of ANNs is artificial neuron, which is the design foundation of ANNs and its model is indicated in Fig.1.

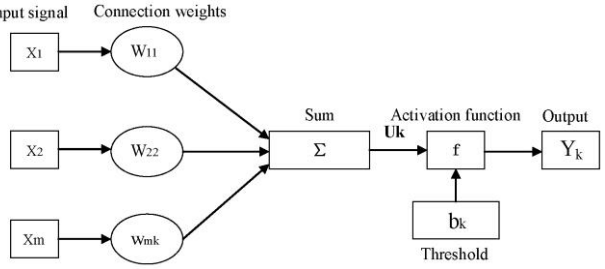

FIGURE 1 Artificial neuron model

An artificial neuron k can be indicated with the following formula.

$$u_k=\sum_{i=1}^{m}w_{ik}x_i \qquad y_k=f(u_k+b_k). \quad (5)$$

In this formula, m is the number of input signals; $x_i(i=1,\ldots,m)$ is the input signal; $w_{ij}(i=1,\ldots,m)$ is the synaptic weight of neuron k (the positive value is at the excited state and the negative value is at the depressed state); u_k is the output of linear combiner of the input signal; b_k is the bias (threshold) of the neuron unit; f is the activation function and y_k is the neuron output signal.

Organize numerous neurons with simple functions through certain topological structure and form the colony parallel processing computing structure. This is the artificial neural network.

According to different connection types, neural network can be divided into two types: layered and interconnected neural network. The layered neural network divides all the neurons into several layers, including input layer, hidden layer and output layer and every layer has some neurons. According to the feedback relationship between layers, the layered neural network can also be divided into the simple feed-forward network, the feedback feed-forward network and the inlayer interconnected feed-forward network. The topological

structure of the layered neural network is demonstrated in Fig.2.

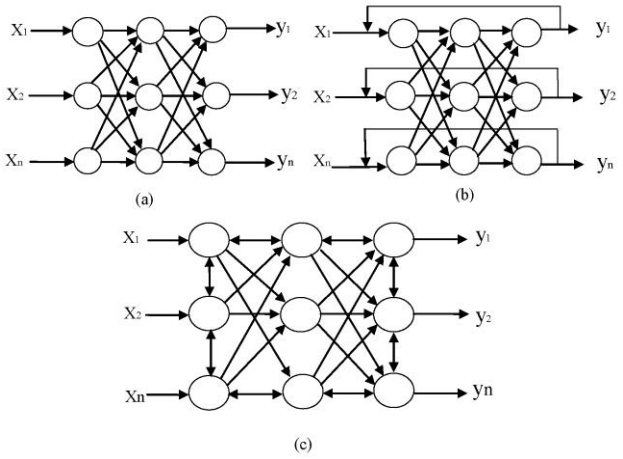

FIGURE 2 The topological structure of layered neural network

a) Simple Feed-Forward Network b)Feed-Forward Network with Feedback c) Inlayer Interconnected Feed-Forward Network

The difference between the interconnected neural network and the layered neural network is that any two units in the interconnected neural network is accessible. According to whether the output of every neuron is connected with other neurons, neural network can also be divided as: fully-connected network and locally-connected network. The topological structure of the interconnected neural network is shown in Fig.3.

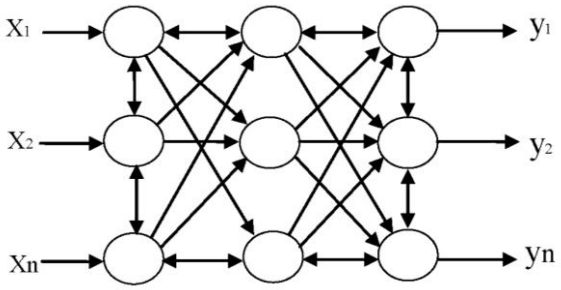

FIGURE 3 The topological structure of interconnected neural network

The basic attributes of neural network reflect the characteristics of neural network. The main characteristics of neural network include:

(1) It has strong robustness and fault tolerance because the information of neural network is distributed and saved in neurons with different network positions.

(2) It has strong information synthesization ability. Every neuron of neural network can process and save information; can handle quantitative and qualitative information and can better coordinate several input information relationships.

(3) It uses parallel processing method. Every neuron in the neural network is parallel in structure and similar processing can be conducted at the same time according to the information received to make faster computing rate.

(4) It has the advantages of self-study, self-organization and self-adaptation. The neurons of the neural network are connected in various ways and the connection strength changes by learning the training samples to make the neural network can handle uncertain systems.

(5) Neural network can fully get close to any complicated non-linear relationship.

3.2 THE NEURAL NETWORK LEARNING ALGORITHM BASED ON ANT COLONY OPTIMIZATION

The basic idea of ACA optimization neural network is to assume that there are N parameters in the neural network to be optimized, including all the weights and thresholds. Firstly, sort these parameters and form a collection I_{pi} of all the possible solutions for the parameter $p_i(1 \le i \le N)$. Then define that m ants go to find food from the ant nest. Every ant starts from the first collection and chooses one element from every collection I_{pi} according to the information status of every element and adjusts the corresponding pheromone to the selected element. When the ant has finished choosing the elements in all the collections, it has arrived at the food source and goes back to the nest in the previous path and adjusts the relevant pheromone. After continuous iteration of the ant, the optimal solution for the parameter can finally be found.

Because BP algorithm is easily trapped in local minimum, this paper has adopted the max-min ant system training neural network which can better solve problems and which has drawn most attention in the improved ant colony algorithm. The neural network training can be seen as an optimization problem, namely to find a group of optimal real number weight combination to minimize the error between the output result and the expected result in this weight. The main steps of the ant colony algorithm optimization neural network are classified as follows:

Step 1: Initialize the pheromone. Equally divide into spn the weight range $[W_{\min}, W_{\max}]$ and the point of every sub-region boundary is an alternative weight. In the initial moment, every point has the same pheromone τ_0. Set the pheromone volatilization coefficient as ρ; the pheromone increment intensity as Q; the maximum iterations N_{ACO} of ant colony optimization algorithm as and the learning rate of BP algorithm as η.

Set the maximum iterations of BP algorithm as N_{BP}; the training error exit criteria as E_0 and the retaining number of the optimal solutions as σ. The number of ants is m and all of them are in the ant nest.

Step 2: Any ant $k(k = 1, \cdots, m)$ starts from the first collection and moves from one point to another according to the probability computed by the following formula.

$$prob(\tau_i^k) = \tau(i) / \sum_{j=1}^{m} \tau(j) . \quad (6)$$

The ant records the marks in the passing points, namely to choose a numerical value for the weight and records them in $tabu_k$. When the ant has chosen values for all the weight parameters, it has completed one traversal and all the recorded values have become the parameters of this neural network. Input the training sample; get the corresponding output and compute the error E.

Step 3: Record the σ th group of weights with fewer errors and adjust the pheromone of every element according to the following formula. Assume that the above-mentioned ant has gone through n time units in its foraging.

$$\tau_j(t+n) = (1-\rho)\tau_j(t) + \Delta\tau_j(t), \tag{7}$$

$$\Delta\tau_j(t) = \sum_{k=1}^{m} \Delta\tau_j^k(t). \tag{8}$$

In the above formulas, $\Delta\tau_j^k(t)$ is the pheromone the k th ant has left on the j th element of this collection in this cycle and it can be computed according to the following formula.

$$\Delta\tau_j^k(t) = \begin{cases} \dfrac{Q}{e}, & \text{Select jth element of the set} \\ & \text{if the ant k in this loop} \\ 0, & \text{Else} \end{cases}. \tag{9}$$

In this formula, Q is a constant and is the pheromone increment intensity and e is the maximum output error when the element chosen by all the ants is seen as the weight of the neural network, which can be defined as $e = \max_{n=1}^{s} \left| O_n - O_p \right|$. In addition, s is the number of samples and O_n and O_q are the actual output and the expected output of the neural network respectively. Therefore, it can be seen that the fewer the error, the more pheromone increment [8].

Step 4: Repeat the above steps until all the ants have converged to a path, namely having found the optimal solution of the parameters and the cycle ends. The flow chart for the training neural network of ant colony algorithm is shown as Fig.4.

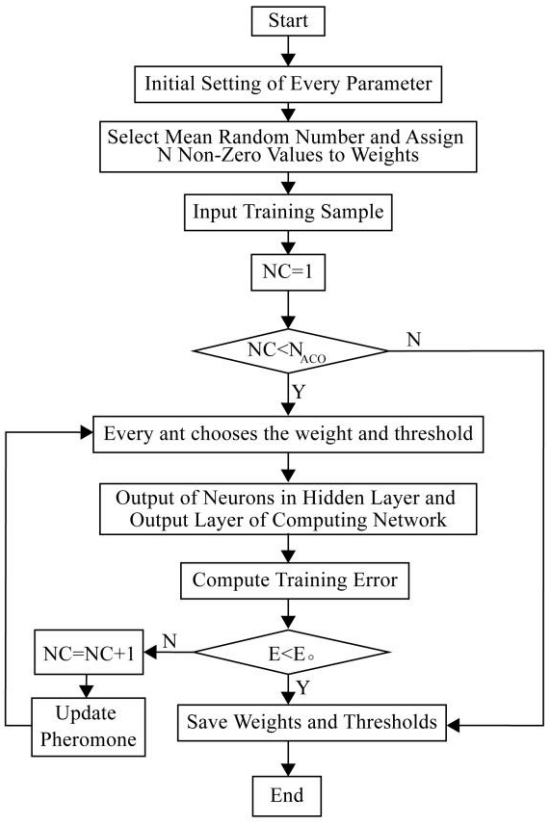

FIGURE 4 The flow chart for training neural network of ant colony algorithm

In this paper, we solve the classification problems with ant colony algorithm and the traditional BP algorithm separately and use the most commonly-used Iris data collection in the public database as the pattern classification data collection with UCI machine. Train the weights and thresholds of the neural networks with ant colony algorithm and the traditional BP algorithm and make comparisons of the results. The neural network in the simulation experiment is the three-layer neural network with a structure of 4-10-3. The algorithm parameters are set as follows: the number of ants S=50; the pheromone volatilization coefficient ρ=0.02 and the total information amount Q=30. The random value of the network weight parameter ranges from -5 to 5. Take the maximum iterations as the end condition of the algorithm. The test error, the classification accuracy and CPU running time in the training phase are displayed in the following table.

TABLE 1 Performance comparison of neural network training

	Test error	**Classification accuracy (%)**	**CPU running time (s)**
Ant colony optimization algorithm	1.353	96.25	20.28
Traditional BP algorithm	2.734	93.68	37.17

It can be seen from the table that ant colony optimization algorithm has fast convergence rate at the training phase and high error precision.

4 Conclusion

Although ant colony algorithm has made big breakthroughs in many application fields since its appearance, there are still some problems about ant colony algorithm to be settled in its practical applications. This paper explains the basic principles and typical characteristics of ant colony algorithm in detail; briefly introduces the model structure and learning algorithm of BP neural network; explores the establishment and optimization algorithm of the optimization neural networks of ant colony algorithm; finishes the network training and test data diagnosis with the extractive samples; makes comparative analysis with the training process and results of BP neural networks and proves the advantages of ant colony optimization neural network.

An improved algorithm for multi-factor fuzzy correlation

Chang Liu, Zhenyu Na*, Xin Zhang

School of Information Science and Technology, Dalian Maritime University, Dalian 116026, Liaoning, China

Received 1 June 2014, www.cmnt.lv

Abstract

As a means for Vessel Traffic Service (VTS) to oversee the vessels, the traditional radar and the new navigation method of Automatic Identification System (AIS) are the two sources of getting the vessels' information. Tracks Fusion of the data received from these two sensors becomes the fundamental problem to be resolved in VTS. The tracks correlation is the premise and basis of the tracks fusion. This paper proposed an improved algorithm of multi-factor integrated fuzzy correlation based on the least square-time interpolation. We make generous correlation decision of distance and achieve the targets set in a fixed range, and then after time correction based on the least square-time interpolation we get the correlated tracks set and make fuzzy correlation used the membership function of normal distribution. The simulation experiment shows the proposed fuzzy correlation algorithm is more precise and the data are more close to the actual data of the vessel. The result of this effort can become an efficient method that impacts greatly on the vessel traffic management.

Keywords: Fuzzy Correlation, Tracks Fusion, Automatic Identification System (AIS)

1 Introduction

The VTS (Vessel Traffic Service) is a system of receiving and processing the traffic data, and providing vessels with service. Up to now, many VTS systems have been introduced in world-wide ports. In China, there have been 22 VTS systems covering most of the water area. VTS played an important role in traffic safety, efficiency and environmental protection [1-2]. In VTS, radar is the main tool to monitor and collect data [3]. With the establishment of the shore-based AIS (Automatic Identification System) and inter-fusion with VTS, VTS can get target data such as dynamic, static and navigation information [4-7]. For the VTS' of multiple radars, the cross section data can be collected by nearly radars. When the shore-based AIS is involved in the processing, the track data can be achieved by both radar and AIS [8]. For such a condition, we need a multiple sensors processing data fusion method (MSPDF) [9-12]. MSPDF can fuse the data from different sensors and establish the system tracking, which can increase the tracking performance of VTS.

Some research proposed the method of central clustering used in the tracks correlation. Comparing with the method of focal clustering, in this paper, we propose an improved algorithm multi-factor integrated fuzzy correlation based on the least square-time interpolation method. By experiment, we can conclude that the improved method is more precise and the data are more close to the real navigation data of the ship. Firstly, we get to make a correlation decision of distance from AIS and radar and achieve the correlated targets set [13-15]. And next we go for a multi-factor fuzzy correlation algorithm [16-18]. The fuzzy correlation algorithm design the membership functions of the distance and bearing parameters of the target ships from radar and AIS. Finally, by multi-factor integrated fuzzy correlation we can evaluate the correlation tracks and then make fusion of them. This approach is more effective and accurate especially in the busy water area with high density of ships. To do so, the remainder of this paper is outlined as follows. In the next section, we present the idea of generous correlation of distance and time correction. In Section 3, we have developed an approach to fuzzy correlation based on normal distribution membership function. In Section 4, the fusion method is offered. In section 5, we make the simulation and analyse the result. In Section 6, we close the paper and give some remarks.

2 Decision of distance correlation and time correction

First according to the data characteristic of radar and AIS we should make the distance correlation and time correction.

2.1 DISTANCE CORRELATION

Suppose the position of ship A detected by radar is ($X_{A(t)}$, $Y_{A(t)}$), and the speed is $v_{A(t)}$. Here we suppose ship A is of uniform linear motion. According to the speed at the time we can get the AIS report period T_a of ship A. If the tracks of AIS and radar are correlated at time *t*, the track of AIS should be within the circle of radius *R*, shown as in Figure 1.

* ***Corresponding author*** e-mail: nazhenyu@dlmu.edu.cn

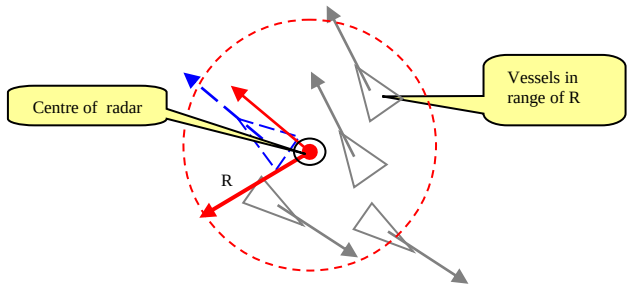

FIGURE 1 Distance correlation

We define *R* as in Equation (1).

$$R = v_{A(t)}T_a + \delta_r + \delta_a . \tag{1}$$

In Equation (1), δ_r and δ_a are the distance errors of radar and AIS. We correlate the tracks set *l* of radar with the tracks set l^* detected by AIS. So *S*(*l*) is defined as the correlation tracks set of the ship. See Equation (2).

$$S(l) = \{l^* \mid d\left(l(t), l^*(t)\right) \le R\}. \tag{2}$$

In Equation (2), $l(t)$ is the track-point of time *t*, beginning from 1. And $d(x, y)$ is the distance of *x* and *y*.

2.2 TIME CORRECTION BASED ON THE LEAST SQUARE- INTERPOLATION METHOD

Tracks of targets from radar and AIS may be not at the same sample time. So we define a sample time set, and the sample time of all the targets should be corrected by the method of interpolation according to the definition set in order to obtain the position set of them at the same time. The interpolation equation is illustrated in Equation (3).

$$\begin{cases} x_c = v_x \Delta T + x_0 \\ y_c = v_y \Delta T + y_0 \end{cases}. \tag{3}$$

In (3) x_c and y_c are the corrected coordinated value of distance (*x*, *y*); v_x and v_y are the speed component of (*x*, *y*); ΔT is the time difference of the original sample time; and x_o, y_o are the original distance value of direction (*x*, *y*). We select the cubic spline function to make the curve smooth. Suppose $(n+1)$ measurement in the time interval of $[a,b]$ for the targets from radar or AIS, and then divide the time interval of $[a,b]$ into $a \le x_0 \le x_1 \le x_2 \le x_3 \le \cdots \le x_n \le b$. The sample time is x_i $(i = 0,1,2,\cdots,n-1)$. The measurement value of $y_i = f(x_i)$ $(i = 0,1,2,\cdots,n-1)$ for each x_i can be the target speed or distance. We can construct the cubic spline interpolation function $S(x)$, satisfying the three conditions as follows.

(1) $S(x_i) = y_i, i = 0,1,2,\cdots,n-1$.

(2) in each $[x_i, x_{i+1}]$ $(i = 0,1,2,\cdots,n-1)$, $S(x)$ is a cubic polynomial.

(3) $S(x)$ has the continuous second derivative in $[a,b]$.

According to each measurement value $(x_i, y_i)(i = 0,1,\cdots,n-1)$ we make the $f(x_i) = y_i$ satisfying the Equation (4).

$$\sum_{i=0}^{n} (S^*(x_i) - y_i) = \min . \tag{4}$$

Comparing with the method of central clustering, the data of least square-interpolation method is more close to the actual data of the navigation ship.

3 Multi-factor fuzzy correlation algorithm

3.1 FUZZY FACTORS SET

We take the Euclidean distance of positions and bearings of vessels as the factors of a fuzzy set, as shown in Equation (5) and Equation (6).

$$U = \{u_1, u_2\}, \tag{5}$$

$$\begin{cases} u_1(t) = \left[\left(x_r(t) - x_a(t)\right)^2 + \left(y_r(l) - y_a(t)\right)^2\right]^{\frac{1}{2}} \\ u_2(t) = \left|\arctan\left[y_r(t)/x_r(t)\right] - \arctan\left[y_a(t)/x_a(t)\right]\right| \end{cases}. \tag{6}$$

$u_1(t)$ and $u_2(t)$ are respectively the differences of Euclidean distance and the bearing at the sample time of *t* from two targets. $x_r(t)$ and $y_r(t)$ are respectively the position components of (*x*, *y*) from radar at the time *t*. $x_a(t)$ and $y_a(t)$ are respectively the position components of (*x*, *y*) from AIS at the time *t*.

In order to simplify the calculation we set the evaluation set only two conditions as *V*.

$$V = \{\text{Correlation}, \text{Non-correlation}\}. \tag{7}$$

3.2 FUZZY CORRELATION OF SINGLE-FACTOR EVALUATION

We set the single parameter fuzzy array as in Equation (8).

$$R = (r_{kl})_{n\times m}(l = 1, 2). \tag{8}$$

In Equation (8) r_{kl} means the possibility of the correlation result *l* of the two tracks considering the parameter *k*. This is the single parameter correlation membership. r_{k1} is the correlation membership and r_{k2} is the non-correlation membership. We select Normal distribution membership in the algorithm as shown in Equation (9).

$$\begin{cases} r_{k1} = \exp\left\{-\tau_k \left(u_k^{\ 2} / \sigma_k^{\ 2}\right)\right\}, k = 1,2 \\ r_{k2} = 1 - \exp\left\{-\tau_k \left(u_k^{\ 2} / \sigma_k^{\ 2}\right)\right\}, k = 1,2 \end{cases}. \quad (9)$$

In equation (9) τ_k is correction modulus. That is, τ_1 and τ_2 are respectively the correction modulus of position and bearing. $\sigma_k^{\ 2}$ is the variance. $\sigma_1^{\ 2}$ and $\sigma_2^{\ 2}$ are respectively the precision variance of position and bearing.

The fuzzy evaluation array of single-factor is indicated by Equation (10).

$$R = \begin{bmatrix} r_{11} & r_{12} \\ r_{21} & r_{22} \end{bmatrix}. \quad (10)$$

3.3 FUZZY CORRELATION OF MULTI-FACTOR EVALUATION

The weighting fuzzy set is described as in (11).

$$A = (a_1, a_2). \quad (11)$$

Here considering the precision of position is higher than that of bearing we set a_1 as 0.6 and a_2 as 0.4 according to the experience by many experiments.

The fuzzy correlation evaluation of two tracks depends on the weighted fuzzy set A and the fuzzy evaluation array of single parameter R. So the intenerated fuzzy set is defined as in (12).

$$B = A \bullet R = (b_l) = (b_1, b_2). \quad (12)$$

In Equation (12) b_1 and b_2 are respectively the membership of correlation and non-correlation. We adopted the weighted average method to integrate the fuzzy sets, as showed in Equation (13).

$$\begin{cases} b_1 = a_1 r_{11} + a_2 r_{21} \\ b_2 = a_1 r_{12} + a_2 r_{22} \end{cases}. \quad (13)$$

We define a threshold Td_g to evaluate the membership b_1. When it satisfied with the Equation (14), we take the decision of the correlation.

$$b_1 > Td_g. \quad (14)$$

4 Tracks fusion

4.1 WEIGHTED MODULUS

Here we adopt the statistics weighted estimation algorithm. The data fusion is according to the precision of data from radar and AIS. The higher the precision is, the greater the weight is.

$$\begin{cases} W_{RL} = \dfrac{\sigma_{AL}^{\ 2}}{\sigma_{AL}^{\ 2} + \sigma_{RL}^{\ 2}} \\ W_{AL} = \dfrac{\sigma_{RL}^{\ 2}}{\sigma_{AL}^{\ 2} + \sigma_{RL}^{\ 2}} \end{cases}. \quad (15)$$

In Equation (15), $W_{AL} + W_{RL} = 1$. σ_{RL} and σ_{AL} are respectively the precision of radar and AIS. According to the experience we set σ_{RL} and σ_{AL} as 15 m and 8 m.

4.2 WEIGHTED FUSION

By equation (15) we can get the fusion track l in Cartesian coordinates. See Equation (16).

$$\begin{cases} L_x = W_{RL} L_{Rx} + W_{AL} L_{Ax} \\ L_y = W_{RL} L_{Ry} + W_{AL} L_{Ay} \end{cases}. \quad (16)$$

$L_{R(x,y)}$ and $L_{A\,(x,y)}$ are the position values of radar and AIS.

5 Experiment and analysis

5.1 PARAMETERS OF THE TRACKS FROM RADAR AND AIS

We suppose three tracks of targets A, B and C from radar, and one track from AIS.

(1) The speed of ship A in direction (x, y) are respectively $v_{xA} = 10$, v_{yA} = 0. The track of ship A from radar is shown in Table 1. x_{RA} *and* y_{RA} are respectively the position data of ship A from radar.

5.2 FUZZY CORRELATION SIMULATION

Firstly, by the distance correlation we can see the tracks of A and B are out of the threshold, and the track of C is within the threshold, so we continue the fuzzy correlation decision of C with AIS track.

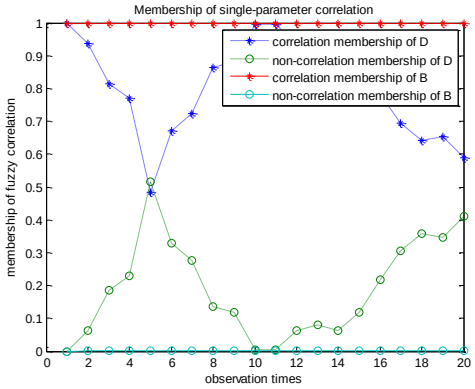

FIGURE 2 Single-factor correlation results

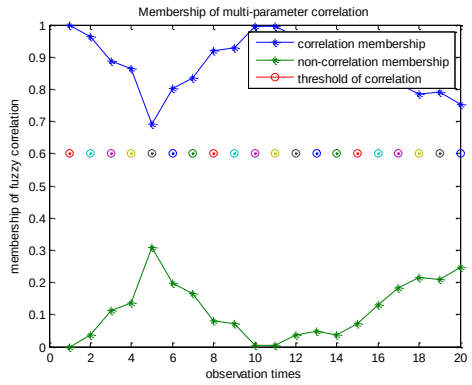

FIGURE 3 Multi-factor correlation results

After the time correction of track C and AIS, we got the correlation membership of a single parameter as showed in Figure 2 and the multi-factor correlation in Figure 3. From Figure 2 the correlation membership of D (distance) is greater than 50% and the correlation membership of B (bearing) is 100%. From Figure 3 fuzzy correlation membership of multi-factor exceeds the threshold of 0.6 as we set. It can be seen obviously that track C is related to the track of AIS.

The fusion track of ship C and the original tracks of A, B is shown in Figure 4. We can see the fusion track is the same as the track of AIS, because the precision of AIS is much higher than that of radar.

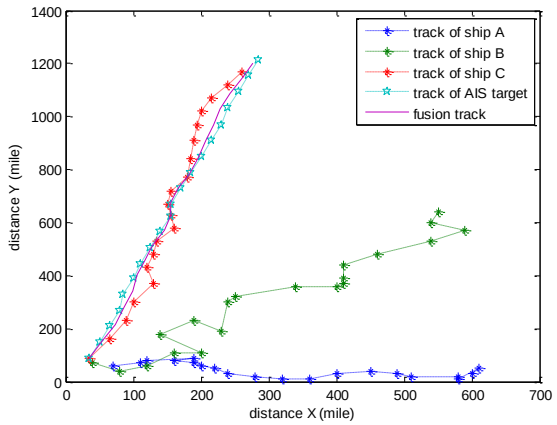

FIGURE 4 Fusion track of C and AIS

We make the experiments for the comparison of the two correlation methods, one is based on the least square-interpolation and the other is the central clustering, the Standard deviation is shown in table 5. From table 5 we can conclude that the correlation algorithm based on the least square- interpolation time corrected is more precise.

TABLE 5 Comparison of standard deviation of the two methods for the time corrected

Method	AIS	radar	fusion
central clustering	1.4308	7.8015	1.5908
least square- interpolation	1.4025	6.9446	1.3091

6 Conclusions

This paper described a fuzzy correlation algorithm to fuse redundant observations to multi-sensor coverage in order to provide an accuracy track of AIS and radar in the Vessel Traffic Service (VTS) and make the navigation safety. The experiment showed that the improved algorithm correctly fuses the redundant sensor observation on the same target and the result is a computationally efficiency and cost effective software solution to a deficiency that impacts greatly on overall waterway safety and protect the ocean environment. The correlation algorithm can be enhanced by adding other attributes such as speed, course, size and track quality to improve the accuracy and reliability of the method.

Abstract

Based on the metamorphic mechanisms, we proposed a new type of metamorphic kinematic pair, with which a novel metamorphic parallel cutting mechanism was designed to achieve changing pose and trajectory movement. Using the screw theory and the product of exponentials formula, we constructed a nonlinear system of equations for each configuration framework of the metamorphic parallel cutting mechanism, and the Sylvester resultant elimination method was employed to simplify equations of motion for the mechanism, thereby completing the research about the forward and inverse kinematics solution of the original and sub-configuration framework and verifying the feasibility of this novel mechanism via MATLAB and ADAMS simulation.

Keywords: Metamorphic Mechanism; Screw Theory; Product of Exponentials Formula; Forward and Inverse Kinematics Solution

1 Introduction

The manufacturing of ship products is often accompanied by large-diameter hole cutting and processing on the hull surfaces, which are pieced together with complex surface patches in most cases. And then square groove or bevel preparation of these large size holes are often needed [1-2]. As a critical technical problem in shipbuilding industry, large-diameter-hole and changing-angle bevel structure processing is characterized by high difficulty, low efficiency and low accuracy, etc., and the processing quality of which will directly influence the quality and efficiency of the subsequent industrial processes.

Seamus Gordon, et al., from University of Limerick, designed a high-speed CNC cutting machine realizing spatial movement of the cutting tool along three axial directions. Controlled by computer numerical control programming, the high speed of this cutting device reaches 40m/min [3]. The Omnimat cutting machine developed and produced by Messer, is a high-performance, multi-functional, large CNC cutting machine applicable for high speed and precision cutting of large size flat plate [4]. The model RV-016 cutting robot, developed and produced by Panasonic Corporation, adopts a serial mechanism, and its end infinite rotating cutting gun can perform high speed and precision cutting task on complex surfaces.

In China, many experts and engineering technicians in machinery manufacturing field have made a series of researches on numerical control cutting technology. The multi-functional NC-fair incision machine with a gantry-bridge structure, designed by Ming, et al., can cut large 5000mm × 3000mm work-piece and perform arbitrary plane curve cutting tasks [5]. The cantilever structured CNC large intersecting circle flame cutting machine with five-bar cooperating, designed by Sun, et al., can process a work-piece with a diameter of 4000-8000mm (pipe); and the diameter of the cutting hole lies in a range of 50-550mm, and the bevel angle is between 30° and 40° [6]. Zhang, from Harbin Engineering University, designed a large complex surface cutting mechanism with the end cutting torch being a five-bar metamorphic mechanism to achieve square groove and bevel groove of large diameter hole cutting on complex surfaces; controlled by electric motor, it can perform spatial movements with changing pose and trajectory [7].

Based on the analysis of literatures at home and abroad, we know there are two types of cutting techniques and equipment: one is round hole cutting on a plate with its vertical displacement almost unchanged in the cutting process. And the bevel angle remain unchanged in bevel cutting; the other is CNC pipe-cutting machine, which is applicable for round pipe (whose diameter is less than 1.4m) intersection hole cutting.

The parallel mechanism has the merits of simple high-rigidity structure, high processing speed and accuracy, and is less affected by the inertia, etc. For these advantages over the serial mechanism, it has been widely employed in various processing and manufacturing industries. Furthermore, its end moving platform can many complex spatial motions via multi-axis coordination [8-13]. Studies about metamorphic mechanism starts late, but this mechanism has stimulated the research interests of many scholars for its flexible topology, based on which many tasks can be completed [14-21].

* Corresponding author e-mail: lxl--2002@163.com

According to the principles of metamorphic mechanism, a parallel cutting mechanism was designed to solve the problem of changing pose and trajectory in square groove and bevel groove cutting. Since there are different requirements for the cutting torch motion in the process of cutting different shapes of holes on complex surfaces, we reasonably designed different conFigureuration frameworks of the metamorphic mechanism based on their metamorphic characteristics, which can meet the technology requirements of changing spatial pose and trajectory cutting on large complex surface.

2 Metamorphic Parallel Cutting Mechanism Design

2.1 A NOVEL DESIGN OF SPATIAL METAMORPHIC KINEMATIC PAIR

A conventional spherical pair has three spatial degrees of freedom (DOF). And there are 3 degrees of freedom of rotating between the two components linked by the spherical pair. In actual analysis, the motions of the two components can be simplified as the rotation around the three spatial axes that are perpendicular to each other and also meet the right-hand rule. Therefore, a spatial spherical pair is equivalent to a compound kinematic pair consisting of a Hooke's joint and a revolute pair whose axis is perpendicular to the Hooke's joint axial plane. For a Hooke's joint, the shaft connected with the base is the main shaft, and that connected with the linkage is a counter shaft.

According to the principles of metamorphic mechanism, we designed a slot where the two ends of the counter shaft can slide on the main shaft of Hooke's joint. The counter shaft can be fixed in a certain position as required with a pin; therefore, we can reduce the degree of freedom of the kinematic pair by putting pin into the pinhole located on the revolute pair. Based on the framework before and after metamorphic operation, the novel metamorphic kinematic pair can be classified into four configurations:

(1) The original configuration S_{m3}

Fix the counter shaft in a position perpendicular to the main shaft, and remove the pin on the revolute pair. The kinematic pair has three degrees of freedom and is equivalent to a spatial spherical pair, as shown in Figure. 5(a);

(2) The a-type 2-DOF sub-configuration S_{m2}^{a}

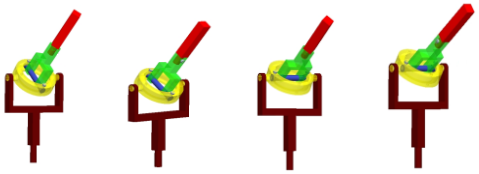
Fix the counter shaft in a position perpendicular to the main shaft, and put the pin into the pin hole on the revolute pair. Now the kinematic pair has two degrees of freedom and is equivalent to a traditional Hooke's joint, as shown in Figure. 5(b);

(3) The b-type 2-DOF sub-configuration S_{m2}^{b}

Fix the counter shaft in a co-axial position with the main shaft, and remove the pin on the revolute pair. Now the kinematic pair has two degrees of freedom, as shown in Figure. 5(c);

(4) Sub-configuration S_{ml} with single degree of freedom

Fix the counter shaft in a co-axial position with the main shaft, and remove the pin on the revolute pair. Now the kinematic pair has only one degrees of freedom and is equivalent to a traditional revolute pair, as shown in Figure 1 (d);



(a) S_{m3} (b) S_{m2}^{a} (c) S_{m2}^{b} (d) S_{m1}

FIGURE 1 The Structure of a Novel Metamorphic Kinematic

2.2 THE METAMORPHIC PARALLEL CUTTING MECHANISM'S ORIGINAL CONFIGURATION FRAMEWORK

Based on the above designed metamorphic kinematic pair unit, a limb kinematic chain where we can switch the degree of freedom is constructed. Assign the position of each kinematic pair, and form the metamorphic parallel mechanism using three same limb chains (see Figure 2). The end effectors $M_1M_2M_3$ are connected with the fixed base $B_1B_2B_3$ via the three same kinematic chains $S_{m2}^{a}S_{m2}^{b}U$. Under this framework, it is 6-DOF mechanism that can achieve upper and lower bevel cutting. Therefore, it is regarded as the original configuration of the cutting machine. When the mechanical properties of the mechanism are considered, the driving input should be as near as possible to the fixed platform to reduce the influence of inertia and to improve load performance. So we choose three Hooke's joints on the fixed platform as driving input.

2.3 THE NOVEL METAMORPHIC PARALLEL MECHANISM'S SUB-CONFIGURATION FRAMEWORK

Based on the original configuration, the 3-DOF sub-configuration framework of metamorphic parallel mechanism is obtained by transforming the metamorphic kinematic pair S_{m2}^{a} into S_{m1} framework, and the metamorphic kinematic pair S_{m2}^{b} into S_{m2}^{a}. Then the limb chain structure changes after these metamorphic operations. The kinematic pair distribution in the limb chain turns into $S_{m1}S_{m2}^{a}U$, which means the sub-configuration framework of the metamorphic parallel cutting mechanism is $3S_{m1}S_{m2}^{a}U$, as shown in Figure 3. With three revolute pairs on the fixed platform chosen

as driving inputs, the square groove cutting on the surface can be achieved.

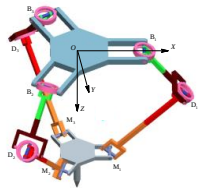


FIGURE 2 The Metamorphic Parallel Mechanism's Original Configuration Framework $3S^a_{m2}S^b_{m2}U$

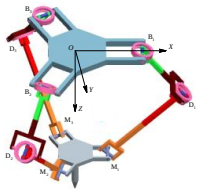

FIGURE 3 3-DOF Sub-configuration Framework $3S_{m1}S^a_{m2}U$

3 The kinematics position analysis of the metamorphic parallel cutting mechanism

3.1 THE ANALYSIS OF THE ORIGINAL CONFIGURATION FORWARD AND INVERSE KINEMATICS SOLUTION

3.1.1 The analysis of original configuration forward kinematics solution

Set the absolute coordinate system $OXYZ$, as shown in Figure 4; the XOY plane is parallel to the plane $B_1B_2B_3$ of the fixed base; axis Z is downward perpendicular to $B_1B_2B_3$; and suppose the origin of coordinates and the geometric centre of $B_1B_2B_3$ overlap. With the structures and parameters of the three limb chains being identical, we assume that: the radius of the circumcircle of $B_1B_2B_3$ is R; the length of $B_iD_i(i=1,2,3)$ is l, and the length of $D_iM_i(i=1,2,3)$ is m. Then suppose the angles of rotation about e_{i1}, e_{i2}, e_{i3}, e_{i4}, e_{i5}, e_{i6} ($i=1\sim3$) in each limb chain are θ_{i1}, θ_{i2}, θ_{i3}, θ_{i4}, θ_{i5} $(i=1\sim3)$ respectively. Let the Hooke's joint of the metamorphic kinematic pair B_i be the driving joint and the rest be driven joint, and $\eta_i(i=1\sim3)$ be the azimuth at point B_i, as shown in Figure 4, where $\eta_1=0^\circ$, $\eta_2=120^\circ$, $\eta_3=$-120°.

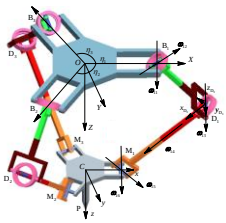

FIGURE 4 The Moving Coordinate System and the Kinematic Screw of the Metamorphic Parallel Cutting Mechanism's Original Configuration Framework

According to rigidity constraint,

$$\begin{aligned}&(M_2-M_1)^T(M_2-M_1)=(M_3-M_1)^T(M_3-M_1)\\&=(M_2-M_3)^T(M_2-M_3)=3r^2\end{aligned}. \quad (1)$$

The coordinates of point M_i in the equation can be obtained through the following methods

$$g_{D_i}(\theta)=e^{\theta_{i1}\hat{\xi}_{i1}^{\omega}}e^{\theta_{i2}\hat{\xi}_{i2}^{\omega}}e^{\theta_{i3}\hat{\xi}_{i3}^{\omega}}g_{D_i}(0), \quad (2)$$

where $e^{\theta\hat{\xi}}=\begin{bmatrix}e^{\theta\hat{e}} & (I-e^{\theta\hat{e}})(e\times v)+\theta ee^Tv\\ 0 & 1\end{bmatrix}$ $(e\neq0)$,

$$\xi=\begin{bmatrix}\omega\\ r\times\omega\end{bmatrix},\quad \hat{\xi}=\begin{bmatrix}\hat{\omega} & r\times\omega\\ 0 & 0\end{bmatrix},\quad \omega=\begin{bmatrix}\omega_1\\ \omega_2\\ \omega_3\end{bmatrix},$$

$$\hat{\omega}=\begin{bmatrix}0 & -\omega_3 & \omega_2\\ \omega_3 & 0 & -\omega_1\\ -\omega_2 & \omega_1 & 0\end{bmatrix}.$$

$$M_i=R_{D_i}(\theta)M_i^{D_i}+t_{D_i}. \quad (3)$$

Substituting (2) and (3) into (1), we have three equations of $\theta_{i3}(i=1\sim3)$:

$$\begin{cases}L_{11}c\theta_{13}c\theta_{23}+L_{12}s\theta_{13}c\theta_{23}+L_{13}c\theta_{13}s\theta_{23}+L_{14}s\theta_{13}s\theta_{23}\\+L_{15}c\theta_{13}+L_{16}c\theta_{23}+L_{17}s\theta_{13}+L_{18}s\theta_{23}+L_{19}=0\\L_{21}c\theta_{13}c\theta_{33}+L_{22}s\theta_{13}c\theta_{23}+L_{23}c\theta_{13}s\theta_{33}+L_{24}s\theta_{13}s\theta_{33}\\+L_{25}c\theta_{13}+L_{26}c\theta_{33}+L_{27}s\theta_{13}+L_{28}s\theta_{33}+L_{29}=0\\L_{31}c\theta_{23}c\theta_{33}+L_{32}s\theta_{23}c\theta_{23}+L_{33}c\theta_{23}s\theta_{33}+L_{34}s\theta_{23}s\theta_{33}\\+L_{35}c\theta_{23}+L_{36}c\theta_{33}+L_{37}s\theta_{23}+L_{38}s\theta_{33}+L_{39}=0\end{cases}, \quad (4)$$

where $L_{mn}(m=1\sim3,n=1\sim9)$ is a polynomial containing $\theta_{i1},\theta_{i2}(i=1\sim3)$.

Based on half-angle formula: $\sin\theta=2\tan(\theta/2)/[1+\tan^2(\theta/2)]$, $\cos\theta=[1-\tan^2(\theta/2))]/[1+\tan^2(\theta/2)]$, supposing $x=\tan(\theta_{13}/2)$, $y=\tan(\theta_{23}/2)$, $z=\tan(\theta_{33}/2)$, and manipulating the above three equations, we have:

$$P_{1y}x^2+P_{2y}x+P_{3y}=0, \quad (5)$$

$$P_{4x}z^2+P_{5x}z+P_{6x}=0, \quad (6)$$

$$P_{4y}z^2+P_{5y}z+P_{6y}=0, \quad (7)$$

where, $P_{1y}=Q_{11}y^2+Q_{13}y+Q_{15}$,

$P_{2y}=Q_{12}y^2+Q_{16}y+Q_{18}$, $P_{3y}=Q_{14}y^2+Q_{17}y+Q_{19}$,

$P_{4x}=Q_{21}x^2+Q_{23}x+Q_{25}$, $P_{5x}=Q_{22}x^2+Q_{26}x+Q_{28}$,

$P_{6x}=Q_{24}x^2+Q_{27}x+Q_{29}$, $P_{4y}=Q_{31}y^2+Q_{33}y+Q_{35}$,

$P_{5y}=Q_{32}y^2+Q_{36}y+Q_{38}$, $P_{6y}=Q_{34}y^2+Q_{37}y+Q_{39}$.

Eliminate the variable z using Sylvester resultant; then regard z and the constant terms as new variables; multiply z with equation (6) and (7), combed with which a matrix is constructed. Since only non-zero solutions are considered, the resultant is zero:

$$\begin{vmatrix} P_{4x} & P_{5x} & P_{6x} & 0 \\ 0 & P_{4x} & P_{5x} & P_{6x} \\ P_{4x} & P_{5x} & P_{6x} & 0 \\ 0 & P_{4x} & P_{5x} & P_{6x} \end{vmatrix} = 0 . \tag{8}$$

Then we have the equation, in which the highest exponent degree of x is not more than 2:

$$F_{1y}x^2 + F_{2y}x + F_{3y} = 0 , \tag{9}$$

where $F_{iy}(i = 1 \sim 3)$ are expressions in which the highest exponent degree of y is 2.

Eliminate the variable x using Sylvester resultant; regard x and the constant terms as new variables; multiply x with equation (5) and (10), combed with which a matrix is constructed. Since only non-zero solutions are considered, the resultant is zero:

$$\begin{vmatrix} P_{1y} & P_{2y} & P_{3y} & 0 \\ 0 & P_{1y} & P_{2y} & P_{3y} \\ F_{1y} & F_{2y} & F_{3y} & 0 \\ 0 & F_{1y} & F_{2y} & F_{3y} \end{vmatrix} = 0 . \tag{10}$$

Then we have the equation in which the highest exponent degree of y is not more than 4:

$$K_4 y^4 + K_3 y^3 + K_2 y^2 + K_1 y + K_0 = 0 , \tag{11}$$

where $K_l(l = 0 \sim 4)$ is a polynomial containing $\theta_{i1}, \theta_{i2}(i = 1 \sim 3)$. θ_{i1}

Because the driving kinematic pair rotation angles θ_{i1}, θ_{i2} are known quantities, the value of y can be calculated out from equation (11). Substituting the y value into equation (5) and (6), we yield twos sets of values of x and z, and then substituting, which into equation (7) to determine the end values of x and z.

After that, the coordinates of M_1, M_2 and M_3 on the end moving platform can be determined, and then we can further determine the pose of the moving platform in the absolute coordinate system.

3.1.2 The analysis of the original configuration inverse kinematics solution

Supposing that the geometric center of the moving platform is *C*, the cutting gun endpoint is *P*, and the length of the cutting gun is n, we set up the moving coordinate system *Cxyz* of the moving platform $M_1M_2M_3$. The x-axis passes through point M_1; z-axis is perpendicular to the moving platform in an outward direction; and y-axis is determined according to right-hand rule. The analysis of original configuration inverse kinematics solution is to determine the driving kinematic pair rotation angle θ_{i1} and $\theta_{i2}(i = 1 \sim 3)$, based on the known pose of the end moving platform $M_1M_2M_3$. Supposing that the moving coordinate system *Cxyz* is formed by rotating the absolute coordinate system along the X-axis, Y-axis and Z-axis by the angles of γ, β, α respectively, the coordinates of C are (x_C, y_C, z_C), and the coordinates of P is $(x_P, y_{P,} z_P)$, the pose of centre of mass (PCM) of the end moving platform is represented as:

$$g_C = \begin{bmatrix} R & t_c \\ 0 & 1 \end{bmatrix} = \begin{bmatrix} e^{Z\alpha} e^{Y\beta} e^{X\gamma} & t_c \\ 0 & 1 \end{bmatrix}$$
$$= \begin{bmatrix} c\alpha c\beta & c\alpha s\beta s\gamma - s\alpha c\gamma & c\alpha c\beta c\gamma + s\alpha s\gamma & x_C \\ s\alpha c\beta & s\alpha s\beta s\gamma + c\alpha c\gamma & s\alpha s\beta c\gamma - c\alpha s\gamma & y_C \\ -s\beta & c\beta s\gamma & c\beta c\gamma & z_C \\ 0 & 0 & 0 & 1 \end{bmatrix} . \tag{12}$$

We calculate out the coordinates of M_1, M_2, M_3, P in the moving coordinate system *Cxyz*: $M_1^C(r,0,0)$, $M_2^C(-\frac{1}{2}r, \frac{\sqrt{3}}{2}r, 0)$, $M_3^C(-\frac{1}{2}r, -\frac{\sqrt{3}}{2}r, 0)$, $P^C(0,0,n)$. Therefore, their coordinates in the absolute coordinate system are:

$$M_i = RM_i^C + t_c , \tag{13}$$

$$P = RP^C + t_c . \tag{14}$$

In solving forward kinematics in the above section, we know point M_1, M_2 and M_3 can be represented by θ_{i1}, θ_{i2}, θ_{i3} $(i = 1 \sim 3)$. Based on the corresponding relationship, we have three square matrix equations:

$$\begin{bmatrix} (c\theta_{11}c\theta_{12}\theta_{13} - s\theta_{11}s\theta_{13})m + lc\theta_{11}c\theta_{12} + R \\ -msc\theta_{12}c\theta_{13} - lsc\theta_{12} \\ -(s\theta_{12}c\theta_{13}c\theta_{13} + c\theta_{11}s\theta_{13})m - ls\theta_{11}c\theta_{12} \end{bmatrix} = \begin{bmatrix} rc\alpha c\beta + x_C \\ rs\alpha c\beta + y_C \\ -rs\beta + z_C \end{bmatrix} . \tag{15}$$

$$\begin{bmatrix} p_1 & q_1 & k_1 \end{bmatrix}^T = \begin{bmatrix} d_1 & e_1 & f_1 \end{bmatrix}^T , \tag{16}$$

$$\begin{bmatrix} p_2 & q_2 & k_2 \end{bmatrix}^T = \begin{bmatrix} d_2 & e_2 & f_2 \end{bmatrix}^T , \tag{17}$$

where $p_1 = -\left[(c\theta_{21}c\theta_{22}c\theta_{23} - s\theta_{21}s\theta_{23})m + lc\theta_{21}c\theta_{22} + R\right]/2 + \sqrt{3}(ms\theta_{22}c\theta_{23} + ls\theta_{22})/2$,

$q_1 = \sqrt{3}\left[(c\theta_{21}c\theta_{22}c\theta_{23} - s\theta_{21}s\theta_{23})m + lc\theta_{21}c\theta_{22} + R\right]/2 + (ms\theta_{22}c\theta_{23} + ls\theta_{22})/2$

$k_1 = -(s\theta_{21}c\theta_{22}c\theta_{23} + c\theta_{21}s\theta_{23})m - ls\theta_{21}c\theta_{22}$,

$$d_1 = -\gamma c\alpha c\beta/2 + \sqrt{3}\gamma(c\alpha s\beta s\gamma - s\alpha c\gamma)/2 + x_C$$
$$e_1 = -\gamma s\alpha c\beta/2 + \sqrt{3}\gamma(s\alpha s\beta s\gamma + c\alpha c\gamma)/2 + y_C \quad ,$$
$$f_1 = rs\beta/2 + \sqrt{3}rc\beta s\gamma/2 + z_C \quad ,$$
$$f_2 = rs\beta/2 - \sqrt{3}rc\beta s\gamma/2 + z_C$$
$$k_2 = -(s\theta_{31}c\theta_{32}c\theta_{33} + c\theta_{31}s\theta_{33})m - ls\theta_{31}c\theta_{32}$$
$$d_2 = -rc\alpha c\beta/2 - \sqrt{3}r(c\alpha s\beta s\gamma - s\alpha c\gamma)/2 + x_C$$
$$p_2 = -[(c\theta_{31}c\theta_{32}c\theta_{33} - s\theta_{31}s\theta_{33})m + lc\theta_{31}c\theta_{32} + R]/2$$
$$-\sqrt{3}(ms\theta_{32}c\theta_{33} + ls\theta_{32})/2$$
$$q_2 = -\sqrt{3}[(c\theta_{31}c\theta_{32}c\theta_{33} - s\theta_{31}s\theta_{33})m + lc\theta_{31}c\theta_{32} + R]/2$$
$$+(ms\theta_{32}c\theta_{33} + ls\theta_{32})/2$$
$$e_2 = -rs\alpha c\beta/2 - \sqrt{3}r(s\alpha s\beta s\gamma + c\alpha c\gamma)/2 + y_C$$

Based on the coordinates of P in the coordinate system, the coordinates of the centre of mass C of the moving platform can be calculated out. And based on equation (15), (16) and (17), values of θ_{i1}, θ_{i2} and $\theta_{i3}\,(i=1\sim3)$ can be calculated out, thereby deriving the expressions of θ_{i1} and θ_{i2} in terms of α, β, γ, x_P, y_P, z_P. So the inverse kinematics solution is completed.

3.1.3 A numerical example of forward and inverse kinematics solution

Supposing that the geometric parameters of the original configuration framework of the metamorphic parallel cutting mechanism are: $R=1000$mm, $r=800$mm, $l=1000$mm, $m=1400$mm, $n=200$mm, the coordinates of the cutting gun endpoint P in the absolute coordinate system are (1000,0,1973), and the Euler rotation angles (γ,β,α) are (0°, 30°, 0°), we can calculate out the coordinates of the centre of mass C of the moving platform (900,0,1800). Substituting all these known quantity into the matrix equations of (15), (16) and (17), we obtain the values of input crank rotation angles θ_{i1}, $\theta_{i2}\,(i=1\sim3)$, and for more detailed calculation results, see Table 1. It can be seen that the input crank rotation angles $(\theta_{11},\theta_{12},\theta_{21},\theta_{22},\theta_{31},\theta_{32})$=(3.445°, 0°, -95.963°, 23.286°, -95.963°, -23.286°) are reasonable solutions of the inverse kinematics.

TABLE 1 Inverse kinematics solution of the metamorphic parallel cutting mechanism's original configuration framework

C (x_c,y_c,z_c) (γ,β,α)	$(\theta_{11}\quad\theta_{12})$	$(\theta_{21}\quad\theta_{22})$	$(\theta_{31}\quad\theta_{32})$
(900,0,1800) (0°,30°, 0°)	(3.445° 0°)	(-95.963°23.286°)	(-95.963°-23.286°)
	(-130.724° 0°)	(-133.334°23.286°)	(-133.334°-23.286°)
	(-49.337°180°)	(95.963° 156.714°)	(95.963° -156.714°)
	(176.557°180°)	(133.334° 156.714°)	(133.334° -156.714°)

Taken $(\theta_{11},\theta_{12},\theta_{21},\theta_{22},\theta_{31},\theta_{32})$
$=(3.445^\circ,0^\circ,-95.963^\circ,23.286^\circ,-95.963^\circ,-23.286^\circ)$
as the input crank rotation angles of the mechanism, we obtain eight sets of forward kinematics solutions by solving the forward kinematics equation of the mechanism. For more detailed calculation results, see Table 2.

It can be seen that the two sets of x and z values calculated out based on the four sets of y values of equation (11) all satisfy equation (7) and thus are all reasonable solutions. Hence, we obtain eight sets of forward kinematics solutions.

TABLE 2 Forward Kinematics Solution of the Metamorphic Parallel Cutting Mechanism's Sub- configuration Framework

No	θ_{13}	θ_{23}	θ_{33}
1	2.5956	3.0572	3.0572
2	1.1422	3.0572	3.0572
3	1.9517+1.2135i	-2.2954+1.0379i	-2.2954+1.0379i
4	-2.1642+0.7489i	-2.2954+1.0379i	-2.2954+1.0379i
5	1.9516-0.2133i	-2.2954-1.0379i	-2.2954-1.0379i
6	-2.1642-0.7484i	-2.2954-1.0379i	-2.2954-1.0379i
7	2.5728	0.6784	0.6784
8	1.8045	0.6784	0.6784

After calculation, the obtained coordinates of M_1, M_2 and M_3 in the absolute coordinate system are shown in Table 3.

TABLE 3 The Coordinates of M_1, M_2 and M_3 in the Absolute Coordinate System

No	M_1			M_2			M_3		
	x_{M_1}	y_{M_1}	z_{M_1}	x_{M2}	y_{M2}	z_{M2}	x_{M3}	y_{M3}	z_{M3}
1	301.79	0	282.205	301.79	0	282.205	301.79	0	282.205
2	-453.439	0	-1418.2	-453.439	0	-1418.2	-453.439	0	-1418.2
3	272.887	0	268.508	272.887	0	268.508	272.887	0	268.508
4	1592.8	0	1400	1592.8	0	1400	1592.8	0	1400

Based on Table 3 and the equation (15), (16) and (17), we can calculate out the coordinates of the geometric center C and the z-y-x Euler angles of the moving platform, see Table 4.

TABLE 4 The coordinates of the geometric centre C and the z-y-x Euler angles of the moving platform

No	C			α	β x_C	γ y_C
	x_C	y_C	z_C			
1	-411.729	0	-79.67	0°	-411.729	0
2	-663.473	0	-646.41	0°	-663.473	0
3	486.443	0	1387.103	0°	486.443	0
4	899.993	0	1800	0°	899.993	0

Since the phase spaces of the first and the third set of solutions will cause interference in the mechanism, and the phase space of the second set is outside the range of maximum rotation angle $\theta_{i3}(i=1\sim3)$, we give all these three sets of solutions up. Errors resulting from using approximate solutions of inverse kinematics to solve the forward kinematics of the mechanism are small between the fourth set of solutions and the inverse kinematics solutions. Figure 5 is the abbreviated drawing of the mechanism pose of the fourth solutions set, and the corresponding model pose is shown in Figure 6.

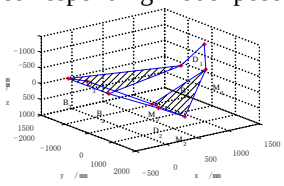

FIGURE 5 Mechanism pose diagram of position positive solutions

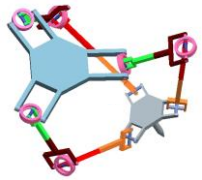

FIGURE 6 Model pose of position positive solutions

3.2 FORWARD AND INVERSE KINEMATIC ANALYSIS OF THE METAMORPHIC PARALLEL CUTTING MECHANISM'S SUB-CONFIGURATION FRAMEWORK

3.2.1 Forward Kinematic Analysis of the Sub-configuration Framework

Figure 7 shows the moving coordinate system and kinematic screw of metamorphic parallel cutting mechanism's the sub-configuration framework. Establish the absolute coordinate system *OXYZ*, and the sub-configuration framework has only 3 degrees of freedom.

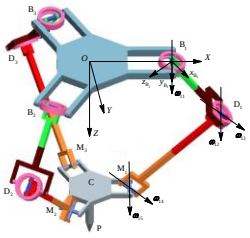

FIGURE 7 Coordinate of motion and twist of sub-configuration

Suppose the angles of rotation about e_{i1}, e_{i2}, e_{i3}, e_{i4}, e_{i5} $(i=1\sim3)$ in each limb chain are θ_{i1}, θ_{i2}, θ_{i3}, θ_{i4}, θ_{i5} $(i=1\sim3)$ respectively. Let metamorphic kinematic pair B_i be the driving joint and the rest be driven joints. Suppose the coordinates of the geometric center C of the moving platform $\mathrm{M_1M_2M_3}$ in the absolute coordinate system are $(x_\mathrm{C}, y_\mathrm{C}, z_\mathrm{C})$, based on which the coordinates of M_1, M_2, M_3 in the absolute coordinate system are :

$$\begin{cases} \mathrm{M}_1=\begin{bmatrix} x_C+r & y_C & z_C \end{bmatrix}^{\mathrm{T}} \\ \mathrm{M}_2=\begin{bmatrix} x_C-r/2 & y_C+\sqrt{3}r/2 & z_C \end{bmatrix}^{\mathrm{T}} \\ \mathrm{M}_3=\begin{bmatrix} x_C-r/2 & y_C-\sqrt{3}r/2 & z_C \end{bmatrix}^{\mathrm{T}} \end{cases}. \tag{18}$$

To calculate the coordinates of D_i in the absolute coordinate system, let fully expanded limb chain $\mathrm{B_iD_iM_i}$ be the initial phase space, at which the conversion between $\mathrm{B}_i x_{Bi} y_{Bi} z_{Bi}$ and the absolute coordinate system is:

$$g_{\mathrm{B}_i}(\theta)=e^{\theta_{i1}\hat{\xi}_{i1}^{\omega}}g_{\mathrm{B}_i}(0). \tag{19}$$

And the coordinates of D_i in the absolute coordinate system are:

$$\mathrm{D}_i=R_{\mathrm{B}i}\mathrm{D}_i^{\mathrm{B}_i}+t_{\mathrm{B}_i}. \tag{20}$$

According to the rigidity constraint equation $\left|\mathrm{D}_i\mathrm{M}_i\right|^2=m^2(i=1\sim3)$, we have the position kinematics equation of the metamorphic parallel mechanism's sub-configuration framework:

$$\begin{cases} (x_c+r-l\cos\theta_{11}-R)^2+y_c^{\,2}+(z_c+l\sin\theta_{11})^2-m^2=0 \\ \left[x_c-\frac{1}{2}r+\frac{1}{2}(l\cos\theta_{21}+R)\right]^2+\left[y_c+\frac{\sqrt{3}}{2}r-\frac{\sqrt{3}}{2}(l\cos\theta_{21}+R)\right]^2+(z_c+l\sin\theta_{21})^2-m^2=0 \\ \left[x_c-\frac{1}{2}r+\frac{1}{2}(l\cos\theta_{31}+R)\right]^2+\left[y_c-\frac{\sqrt{3}}{2}r+\frac{\sqrt{3}}{2}(l\cos\theta_{31}+R)\right]^2+(z_c+l\sin\theta_{31})^2-m^2=0 \end{cases}. \tag{21}$$

Let $a=r-l\cos\theta_{11}-R$, $b=l\sin\theta_{11}$, $e=l\sin\theta_{21}$, $h=l\sin\theta_{31}$, $c=-r/2+(l\cos\theta_{21}+R)/2$, $d=\sqrt{3}r/2-\sqrt{3}(l\cos\theta_{21}+R)/2$, $f=-r/2+(l\cos\theta_{31}+R)/2$, $g=-\sqrt{3}r/2+\sqrt{3}(l\cos\theta_{31}+R)/2$.

So that the simultaneous equations (21) can be written as:

$$\begin{cases} (x_c+a)^2+y_c^{\,2}+(z_c+b)^2-m^2=0 \\ (x_c+c)^2+(y_c+d)^2+(z_c+e)^2-m^2=0 \\ (x_c+f)^2+(y_c+g)^2+(z_c+h)^2-m^2=0 \end{cases}, \tag{22}$$

which can be simplified to a matrix form:

$$2\begin{bmatrix} a-c & -d & b-e \\ a-f & -g & b-h \end{bmatrix}\begin{bmatrix} x_c \\ y_c \\ z_c \end{bmatrix}=\begin{bmatrix} d^2-a^2+c^2-b^2+c^2 \\ g^2-a^2+f^2-b^2+h^2 \end{bmatrix}. \tag{23}$$

Based on equation (23), let z_c represent x_c and y_c, and substitute it into equation (24), thereby deriving the

analytic expression of z_c relative to θ_{11}, θ_{21} and θ_{31}. Then x_c and y_c can be calculated out, and the forward kinematics solution is achieved.

3.2.2 Inverse kinematic analysis of the sub-configuration framework

Substituting the half angle formula $\sin\theta = 2\tan(\theta/2)/[1+\tan^2(\theta/2)]$, $\cos\theta = [1-\tan^2(\theta/2)]/[1+\tan^2(\theta/2)]$ into equation (21), we have the expressions of $\tan(\theta_{11}/2)$, $\tan(\theta_{21}/2)$ and $\tan(\theta_{31}/2)$ about x_c, y_c and z_c, thereby obtaining the input crank rotation angles θ_{11}, θ_{21} and θ_{31}. Then the inverse kinematics solution of the sub-configuration framework is achieved.

3.2.3 A numerical example of forward and inverse kinematics solution

Suppose the coordinates of the cutting gun endpoint P are (1000,0,1000), and the coordinates of the moving platform geometric center C are (1000,0,800). Substituting these two known quantities into equation (21), we have the input crank rotation angles θ_{11}, θ_{21} and θ_{31}. See Table 5 for detailed calculation results. The results $\theta_{11} = -156.033^\circ$ and $\theta_{21} = \theta_{31} = -167.665^\circ$ will cause interference or unreasonably distribution of the components in the mechanism, so we give them up. Then supposing the coordinates of the moving platform geometric center C is (-1000,0,200), $\theta_{11} = -159.101^\circ$ and $\theta_{21} = \theta_{31} = -96.178^\circ$ among the results obtained are also unreasonable and are therefore casted.

TABLE 5 Inverse kinematics solution of the metamorphic parallel mechanism's sub-configuration framework

C(x_c, y_c, z_c)	(1000,0,800)	(-1000.0.200)
θ_{11}	23.174°, -156.033°	-159.101°, -146.005°
θ_{21}	-116.654°, 167.665°	-96.178°, 32.956°
θ_{31}	-116.654°, 167.665°	-96.178°, 32.956°

Taken $(\theta_{11}, \theta_{21}, \theta_{31}) = (23.174^\circ, -116.654^\circ, -116.654^\circ)$ in Table.5 as input crank rotation angles, we obtain the forward kinematics solution by solving the forward position equation of the mechanism. See Table 6 for detailed calculation results.

TABLE 6 Forward Kinematics Solution of Metamorphic Parallel Mechanism's Sub-conFigureuration Framework

$(\theta_{11}, \theta_{21}, \theta_{31})$	(23.174°,-116.654°, -116.654°)
C (x_c, y_c, z_c)	(1006.427,0,995.852) (-280.248,0,-429.140)

Obviously, (1006.427,0,995.852) are reasonable solutions; Figure 8 is the corresponding pose of end moving platform at the model mechanism; Figure 9 is the corresponding pose of the model. Taking the inverse kinematics solution results calculated to the thousandth as the input of forward kinematics solution may result in errors between the forward and the inverse kinematics solution results.

4 Study on kinematics simulation of the metamorphic parallel cutting mechanism

4.1 KINEMATICS SIMULATION OF THE METAMORPHIC PARALLEL CUTTING MECHANISM'S METAMORPHIC ORIGINAL CONFIGURATION FRAMEWORK

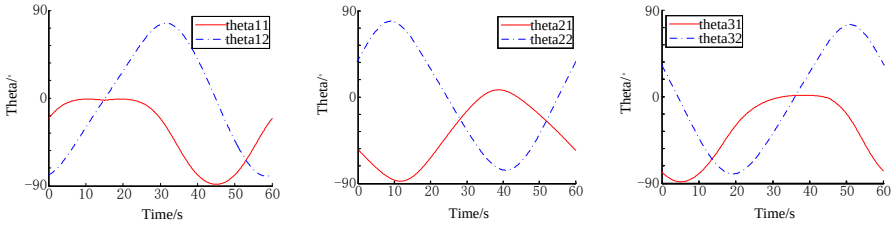
4.1.1 MATLAB-based kinematics numerical simulation of the original configuration framework

The sub-configuration framework of metamorphic parallel cutting mechanism should be able to perform upper and lower bevel cutting on a surface, which means the end moving platform can move with changing spatial pose and trajectory. Now we take upper bevel cutting as an example, and the space motion requirement for the cutting gun endpoint P are:

$$\begin{cases} x = 1000\sin(2\pi t/2) \\ y = 1000\cos(2\pi t/2) \\ z = -400\sin(2\pi t/2) + 1400 \\ \alpha = 0 \\ \beta = -(\pi/6)\cdot\sin(2\pi t/2) \\ \gamma = (\pi/6)\cdot\cos(2\pi t/2) \end{cases}, \tag{24}$$

where T is a time cycle with the value of 60s.

Set 300 evenly spaced numerical points t from 0 to 60s. Based on the above inverse kinematics equation of metamorphic parallel cutting mechanism's original configuration framework, using Matlab, we calculate out the 300 numerical values of the 6 driving kinematics pairs rotation angles in the original configuration framework. Then draw the curve of driving kinematic pair rotation angles to time based on the numerical values obtained. As shown in Figure 10, compute the derivatives of the analytic expressions of the six input crank rotation angles with respect to t, and obtain 300values of inputs angular velocities. Then draw the angular velocity curve, as shown in Figure 11.



(a) Angle changing curve of the drive pair in the branched chain $B_1D_1M_1$ (b) angle changing curve of drive pair in the branched chain $B_2D_2M_2$ (c) angle changing curve of drive pair in the branched chain $B_3D_3M_3$

FIGURE 10 Input angle curve of source configuration of metamorphic parallel cutting mechanism

FIGURE 11 Input angular velocity curve of source configuration of metamorphic parallel cutting mechanism

4.1.2 ADAMS-based kinematics simulation of the original configuration framework

Figure 12 shows the simulation model. Add six driving force on the three Hooke's joints; and draw spline curve using the 300 numerical values of driving kinematic pair rotation angles calculated out by MATLAB and add it as driven spline curve to the AKISPL function. Figure 13 is the spline curve of the input crank rotation angle θ_{11}.

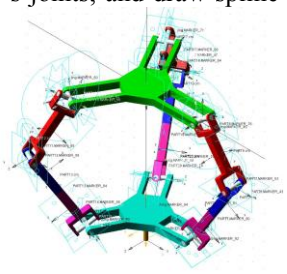

FIGURE 12 Simulation models in ADAMS

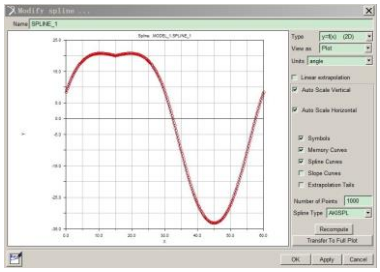

FIGURE 13 The spline curve of input angles

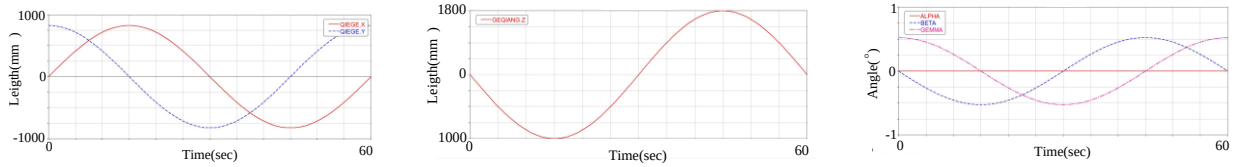
Perform kinematics simulation of the above model by setting the simulation time 60s and the number of time steps 300. And measure the displacement and angle changes of the coordinate system of the end moving platform's center of mass relative to that of the fixed platforms, thereby obtaining the angular displacement and the angular velocity change curves of the end moving platform's center of mass, as shown in Figure 14.



(a) displacement curve on X, Y axis at the end point of cutting gun (b) displacement curve on Z axis at the end point of cutting gun (c) angle curve of the end point of cutting gun relative to system coordinate axis

FIGURE 14 Change curves of displacement and angle of the end moving platform's center relative to the static platform

4.1.3 The simulation output analysis

The curve derived from the simulation shows the ADAMS-based simulation output coincides well with the motion characteristics as well as the changing trend of the center of mass of the mechanism end moving platform with initial settings. To find the numerical errors between the simulation output and the theoretical motion characteristics, the simulation values and theoretical values of the each motion parameters at the time of t=0,10,20,30,40,50,60s are collected, thereby obtaining the maximum relative errors. See Table 7 for more detail.

TABLE 7 The Simulation-theoretical Relative Errors of the Mechanism Motion Parameter

Motion Parameters	X(mm)	Y(mm)	Z(mm)	X-Angle(°)	Y-Angle(°)	Z-Angle(°)
Relative Errors	0.0048	0.0059	0.0005	0.006	0.0021	0.0044

Comparing the ADAMS simulation values and theoretical values of motion parameters of the metamorphic parallel cutting mechanism's original configuration framework, as shown in Table 7, we know the maximum relative errors at each time point are all restricted on a level of 0.01. It means the kinematics method adopted in this paper for the study of the metamorphic parallel cutting mechanism's original configuration framework is correct and reasonable, and the bevel cutting on the surface can be achieved via this mechanism.

4.2 KINEMATICS SIMULATION OF THE METAMORPHIC PARALLEL CUTTING MECHANISM'S SUB-CONFIGURATION FRAMEWORK

4.2.1 MATLAB-based kinematics numerical simulation of the sub-configuration framework

The metamorphic parallel cutting mechanism's sub-configuration framework has 3 degrees of freedom, and the motion of the end moving platform is 3D satisfying the requirement of square groove cutting on a surface.

Now we give the specific requirements for trajectory of the cutting gun endpoint:

$$\begin{cases} x = 1000\sin\dfrac{2\pi}{\mathrm{T}}t \\ y = 1000\cos\dfrac{2\pi}{\mathrm{T}}t \\ z = -400\sin\dfrac{2\pi}{\mathrm{T}}t + 1400 \end{cases}, \tag{25}$$

where T is a time cycle with value of 60s.

Set 300 evenly spaced numerical points t from 0 to 60s. Based on the inverse kinematics equation of the sub-configuration framework, using Matlab, we calculate out the input crank rotation angles and angular velocities at the 300 numerical points, and then draw the curve of input rotation angle and angular velocity to time, as shown in Figure 15 and Figure 16.

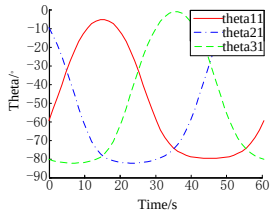


FIGURE 15 The input angle's changing curve of sub configuration

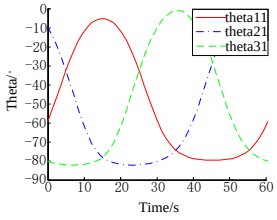

FIGURE 16 The input angular's velocity curve of sub configuration

4.2.2 ADAMS-based kinematics simulation of the sub-configuration framework

The kinematics simulation method applied to the study of the metamorphic parallel cutting mechanism's sub-configuration framework is the same with that applied to the original configuration. And Figure 17 shows the simulation model. Using the same method in section 3.1.2, import the values of the three driving pair rotation angles obtained from MATLAB into ADAMS, and use Spline curve to fit the data points of driving pair rotation angles. Then, set spline-driven pattern for the sub-configuration framework.

Perform kinematics simulation of the above model by setting the simulation time 60s and the number of time steps 300. And measure the displacement and angle changes of the coordinate system of the center of mass of the end moving platform relative to that of the fixed platforms, thereby obtaining the angular displacement and the angular velocity change curves of the center of mass of the end moving platform, as shown in Figure 18.

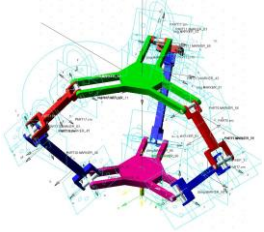

FIGURE 17 The ADAMS Simulation Model

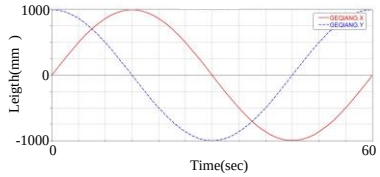
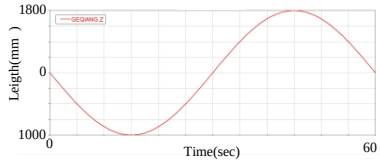


(a) X, Y axis displacement curve of cutting gun end point



(b) Z axis displacement curve of cutting gun end point

FIGURE 18 Each axis displacement curve of the end moving platform's centroid

4.2.3 The simulation output analysis

The analysing method is the same as that applied to the original configuration framework. Similarly, the ADAMS simulation values and theoretical values (motion values of the end moving platform's center of mass in the mechanism with initial settings) of the each motion parameters at the time of t=0,10,20,30,40,50,60s are collected, thereby obtaining the maximum relative errors as shown in Table 8.

TABLE 8 The Simulation-theoretical Relative Errors of the Mechanism's Motion Parameters

Motion Parameters	X(mm)	Y(mm)	Z(mm)
Relative Errors	0.0028	0.0045	0.0013

Comparing the ADAMS simulation value and theoretical value (the mechanism with initial settings) of the motion parameters of the metamorphic parallel cutting mechanism's sub-configuration framework, as

shown in Table 8, we know the maximum relative errors at each time point are all restricted to a level of 0.01. It means the kinematics method adopted in this paper for the study of sub-configuration framework is correct and reasonable, and the bevel cutting on the surface can be achieved via this mechanism.

5 Conclusions

(1) Based on the traditional spherical pair, a novel metamorphic kinematic pair with four different frameworks was designed according to the principles of metamorphic mechanism. And then we devised a metamorphic parallel cutting mechanism structure using this kinematic pair.

(2) We analysed the forward and the inverse kinematics solution for the original and the sub-configuration of the metamorphic parallel cutting mechanism respectively, and made numerical example verification using MATLAB. Finally, the ADAMS simulation showed that this novel metamorphic parallel cutting mechanism is capable of square groove and bevel cutting on complex surfaces satisfying the technical requirements of changing spatial pose and trajectory cutting on complex large-size surfaces.

Test paper composition based on fish swarm algorithm

Wenfa Wang*, Shiyao Wang

Department of Computer Science, Yanan University, Shaanxi, 716000, China

Received 1 May 2014, www.cmnt.lv

Abstract

Fish swarm algorithm was applied to seek optimization solution of test paper composition. Imitation results showed that fish swarm algorithm had better performance than random drawing algorithm in both composition accuracy and running time. The validity and superiority of the algorithm in this work, therefore, were verified.

Keywords: fish swarm algorithm, test paper composition, mathematical model, running time

1 Introduction

Development of intelligent item bank is an important aspect of computer application in educational field. By taking advantage of computer and technology and combining modern educational theory, questions are selected from current bank to automatically generate test questions satisfying teaching and examination requirements.

Currently, there are two main algorithms to solve test paper composition:

1) random search in current question bank for questions satisfying conditions with required amount. With great randomness and disconfirmation, this method is poorly intelligent, which cannot satisfy with education demands;

2) questions extracted for the whole test paper by random drawing. This method, which is relatively inflexible, cannot satisfy the different requirements of question types in papers.

2 Artificial fish swarm algorithm

Proposed by Li Xiaolei, et al. in 2002, Artificial Fish Swarm Algorithm (AFSA) is a new-type biotic optimization algorithm based on research into animal swarm intelligent behaviour. "Generally, the place with the most existing fish in water area is also the place with the most nutrients". According to this characteristic, this algorithm enables optimization to be realized by imitating foraging behaviour of fish swarm.

As a kind of optimizing method based on autonomous animats behaviour, AFSA is a new-type intelligent biotic algorithm built upon activity characteristics of fish swarm.

Fish has following behaviours by observation: foraging behaviour, swarm behaviour, following behaviour, and random behaviour. Because fish behaviours are tightly related to problem solution in this part, a major problem of algorithm implementation will be the adoption of simple and effective methods for constructing and realizing the behaviours.

2.1 BASIC CONCEPT

It is assumed that there is a swarm composed of *N* artificial fish in an n-dimensional target searching space. Status of every artificial fish per day can be expressed as vector quantity $\mathrm{X}=(x_1,x_2,\cdots,x_n)$, in which $x_i\ (i=1,2,\cdots,n)$ is the variable for optimization. Food concentration in current location of artificial fish is expressed as $\mathrm{Y}=f(x)$, while Y is the target function. Figure 1 shows that δ is the factor of congestion degree, step is the step length of artificial fish movement, $d=\|x_i-x_j\|$ represents distance between individuals, try number is the maximum try number for foraging by artificial fish, and visual means perception range of artificial fish.

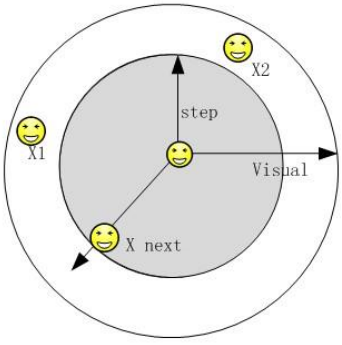

FIGURE 1 Visual field and step length of artificial fish

2.2 BEHAVIOUR DESCRIPTION OF ALGORITHM

1) Random behaviour: means that artificial fish move in visual field randomly. Once the food is found, it will lead the fish towards the direction with increasing foods rapidly.

***Corresponding author** e-mail: ydwangwenfa@126.com

2) Foraging behaviour: means that artificial fish move to a place with more foods. An artificial fish X_i will randomly select a status X_j in visual field, and then their target function values should be calculated, respectively. If Y_j is better than Y_i according to comparison, X_i will move one step to the direction of X_j. Otherwise, X_i should keep selecting status X_j in its visual field until satisfying the forward condition. After repeated try number times, a random step should be taken to give X_i a new status if the forward condition is not satisfied.

3) Swarm behaviour: means that artificial fish gather into a swarm during swimming to ensure their survival and avoid danger. The following three rules should be observed in a swarm. Division rule: is to avoid excessive congestion with neighbouring fish as much as possible. Alignment rule: is to keep consistent average direction to neighbouring fish as much as possible. And cohesion rule: is to move towards the centre of neighbouring fish as much as possible. An artificial fish X_i will search the fish number n_f and central location X_c. When $Y_c / n_f > \delta Y_i$, which represents the optimal and uncrowded status of partner's central location, X_i will move a step towards the central location, or, perform foraging behaviour.

4) Following behaviour: means that artificial fish move to the optimal direction in visual field. An artificial fish X_i will search the optimal partner X_j of function among all partners. When $Y_c / n_f > \delta Y_i$, which represents it is not too crowded around the optimal partner, X_i will move a step towards the central location, or, perform foraging behaviour.

5) Bulletin board: is a space for recording individual status of the optimal artificial fish. The current status of an artificial fish should be compared with recorded status on bulletin board after one time of iteration. When the comparison shows, that the current status is better, the status on bulletin board should be updated with it, or, keep unchanged. The required optimal value is the value on bulletin board outputted after all irritations in the whole algorithm.

2.3 ALGORITHM STEPS

Given that above-mentioned behaviours of artificial fish swarm, every artificial fish will select a behaviour for actual performance by exploring the condition of current environment and its partners. Eventually, artificial fish will gather around several local extremums in different numbers. In discussion of maximum problem, however, artificial fish with larger adaptive value will generally gather around larger extremum field, which is beneficial to obtain overall extremum field. Additionally, a greater number of artificial fish will gather around extremum field in larger value, which is beneficial to estimate and obtain overall extremum. Specific steps of artificial fish swarm algorithm are shown as follows:

Step 1. Swarm scale is determined as *N*, and *N* individuals are randomly generated in feasible region of variable. It is assumed that the visual range of artificial fish is Visual, the step length is Step, the factor of congestion degree is δ, and the try number is try number.

Step 2. Adaptive value of every individual in initial fish swarm is calculated, and the status and its value of the optimal artificial fish will be given to bulletin board.

Step 3. Individual will update itself by behaviours, such as foraging, swarm and following to generate a new fish swarm.

Step 4. All the individuals should be evaluated. The bulletin board should be updated with the individual, which is better.

Step 5. Algorithm will be finished when the optimal solution on bulletin board reaches the satisfying error range, or turn to step 3.

3 Fish swarm algorithm steps for test paper composition

During test paper composition, logic order must be followed to compose a test paper conforming to composition constraints. Specific steps are as Figure 2.

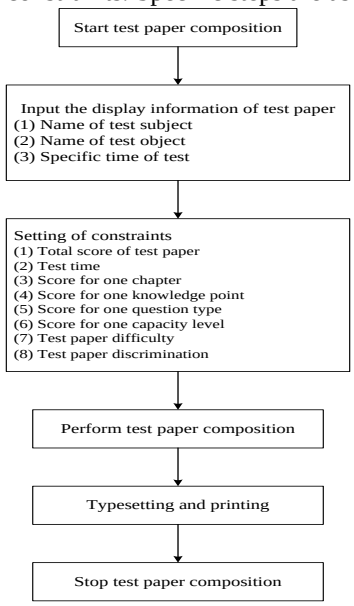

FIGURE 2 Fish swarm algorithm steps for test paper composition

4 Constraints for test paper composition

The objective of test paper composition is enabling test system to automatically select a certain amount of test questions from item bank according to constraints. These questions will compose a test paper satisfying examination requirement, which strives to sincerely and effectively reflect teaching level, and test examinees on mastery degree of relevant knowledge. Thus, test quality can be improved, and test objective can be reached.

Consequently, all the constraints affecting test paper problem should be determined according to examination requirement in composition to reach the objective. Generally, there are following constraints on test paper composition according to above analysis of composition steps:

1) Constraint of knowledge point. Knowledge points in teaching are always corresponding to section content in textbook, so this constraint is also the constraint of chapters. In occupational or other tests, however, constraint of knowledge point means the constraint of professional knowledge.

2) Constraint of question type. Constraint of question type means the question types included in the test paper, that is, question types for test paper composition in the examination.

3) Constraint of question amount. Constraint of question amount is the amount of test questions included in the test paper. Specifically, it is the question amount for one question type. This constraint is positively correlated with answer time

4) Constraint of answer time. Constraint of answer time means the longest time for finishing all the questions in the paper. In general, the longer the answer time is, the greater the question amount is.

5) Constraint of difficulty. Constraint of difficulty means the average difficulty of the test paper and the difficulty of test questions. Generally, test difficulty depends on different test targets. For example, in the test selecting minority of outstanding students, test difficulty should properly increase. In qualification test requiring majority of passers, however, the difficulty should properly reduce. Better effectiveness can be reached only if this constraint combines with the constraint of discrimination.

6) Constraint of discrimination. Constraint of discrimination is the discrimination capability of test paper. Total discrimination of test paper is the average discrimination of all test questions.

7) Constraint of exposure time. This means the test times of knowledge. The more test times, the more times the knowledge point will be repeated.

5 Mathematical model of test paper composition

The above analysis on constraints shows that the system is always limited by some constraints when selecting a test question from item bank in composition. If every constraint is a local constraint, all the constraints, which should be satisfied in the test paper, will constitute global constraint. Four vectors will be defined here:

Attribute set: $s=\{s_1,s_2,\cdots,s_n\}$, which is attribute variable of test question (question type, affiliated section, knowledge point, difficulty factor, score, etc.) or their quantization value;

Value set: $L=\{l_1,l_2,\cdots,l_n\}$, which corresponds to the value range of every attribute variable of test question;

Constraint set: $R=\{r_1,r_2,\cdots,r_n\}$, which corresponds to the constraint relation between different values for attribute variable of test question;

Question set: $I=\{i_1,i_2,\cdots,i_n\}$, which corresponds to the test question selected from item bank and satisfying with certain constraints.

It can be seen that test paper composition is to randomly select a group I from item bank, while the attribute variable *S* of this group should satisfy the constraint of *R* within value range *L*. Automatic test paper composition, therefore, can be described as a problem of multi-constraint objective satisfaction. In addition, the mathematical model of test paper composition can also be considered as a constraint satisfaction problem. The constraints can be divided into hard constraint and soft constraint in type.

5.1 MATHEMATICAL MODEL OF HARD CONSTRAINT

Actually, the test paper composition is to select test questions satisfying all the constraints from item bank. It is assumed that there are m test questions in a test paper, and each of these questions should satisfy n indicators. Therefore, the following *m*n* target matrix is established. (*n*-dimensional vectors include difficulty a_1, question type a_2, section a_3, teaching requirement a_4, time a_5, score a_6, etc. a_i means the indicator No. *i*. *m* refers to question amount in paper.) The matrix is as follows:

$$s=\begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}.$$

In this matrix every line represents one question in item bank, while every list is the attribute value of the question. The target matrix should satisfy the following constraints:

1) $\sum a_{i1} * a_{i6} / 100 = ND$ (difficulty of the whole paper, which is determined by the user of composition), the constraint of difficulty. The determination of question difficulty: scoring rate (d)=1- (average score/full score of the question);

2) $\sum a_{1i} * a_{i2} = m_d$ (m_d is the score of question type *d*), in which $C_{1i}=\begin{cases}1\\0\end{cases}$. If $a_{i2}=d$, take 1 for C_{1i}, otherwise, take 0;

3) $\sum c_{2i} * a_{i3} = Z_h$ (Z_h is the score for section *h*), in which $C_{2i}=\begin{cases}1\\0\end{cases}$. If $a_{i3}=h$, take 1 for C_{2i}, otherwise, take 0;

4) $\sum c_{3i} * a_{i4} = p_k$ (p_k is the score for teaching requirement k), in which $C_{3i}=\begin{cases}1\\0\end{cases}$. If $a_{i2}=k$, take 1 for C_{3i}, otherwise, take 0;

5) $\sum a_{i5} = t$ (t is the test time);

6) $\sum a_{i6} = G$ (G is the total score of test paper).

5.2 MATHEMATICAL MODEL OF SOFT CONSTRAINT

In test paper composition, "hard constraint" is to completely obtain the target value, while "soft constraint" is to incompletely obtain the target value. In practical process, above target functions (1)–(6) are difficult to be completely satisfied. In order to minimize the deviation between target function and target value, a priority should be established based on the importance of every target according to user requirements. All the targets should be ordered in this priority to achieve more targets as much as possible. The imported positive and negative deviation variables represent the parts more and less than target value, respectively. The process of test paper composition, therefore, becomes the solution process of "soft constraint" target value. The multi-target optimization model based on "soft constraint" is established as follows:

$$\min\ z = p_1\left|\sum_{i=1}^{p}\left(da_i^- + da_i^+\right)\right| + \ldots + \mathrm{p}_2\left|\sum_{j=1}^{q}\left(db_j^- + db_j^+\right)\right| .$$

Constraints:

$$\sum_{j=1}^{q}\sum_{k}^{n} f_k x_{ijk} + da_i^- + da_i^+ = a_i , \quad i = 1, 2K, p$$

$$\sum_{i=1}^{p}\sum_{k}^{n} f_k x_{ijk} + db_j^- + db_j^+ = b_j , \quad j = 1, 2K, \mathrm{q} .$$

$$\sum_{i=1}^{p}\sum_{j=1}^{q} x_{ijk} = S_k , \qquad k = 1, 2K, \mathrm{n}$$

In the constraints, p_i, the priority factor, represents relative importance of every target. p_i is always prior to p_i+1 to all values of i, in which i=1, 2,3… x_{ijk} represents the amount of questions with difficulty i, scope j and question type k in the test paper. da_i^- and da_i^+ represent the positive and negative deviation variables for total score of questions with difficulty i, respectively, which correspond to difficulty requirement a_i. db_j^- and db_j^+ represent the positive and negative deviation variables for total score of questions with scope j, respectively, which correspond to scope requirement b_j.

6 Algorithm simulation

Table 1 shows the parameter setting in algorithm simulation with MATLAB software according to algorithm steps and mathematical model of test paper composition:

TABLE 1 Parameter setting for fish swarm algorithm

Parameter	Value	Parameter	Value
Artificial fish swarm	50	Perception distance	1
The maximum iterations	100	Factor of congestion degree	0.618
The maximum try number of foraging	100	Step length of movement	0.1

The result of 100 iterations simulation results shows fish better convergence of the algorithm (see Figure 3).

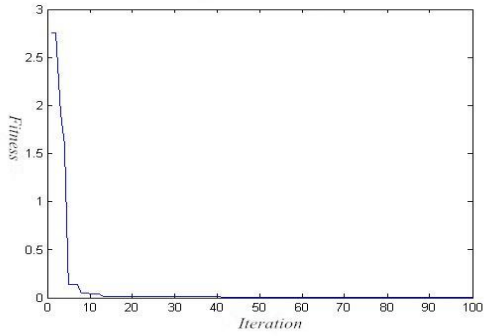

FIGURE 3 Convergence map of fish swarm algorithm

In order to verify the effectiveness and superiority of the algorithm in this work, the algorithm is compared with random drawing in composition accuracy and running time. Figure 4 and Figure 5 show the comparison results:

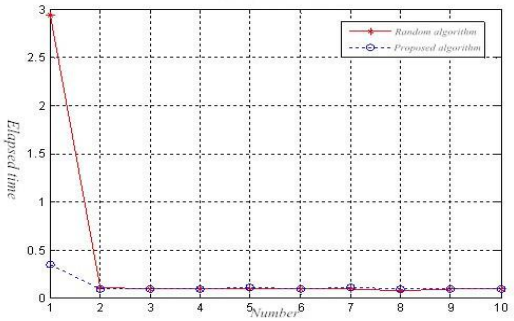

FIGURE 4 Comparison in running time

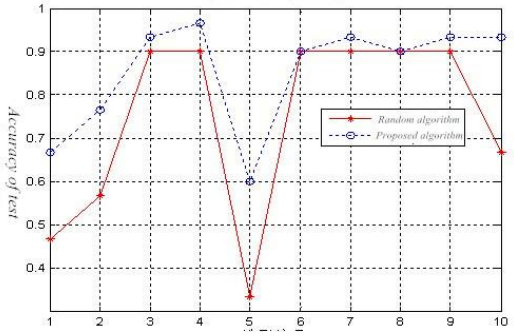

FIGURE 5 Comparison in accuracy

Simulation experiment is conducted by MATLAB software. By comparing with the algorithms in literature, the algorithm in this work is verified in both composition accuracy and running time. It is found in Figure 3 that the accuracy of fish swarm algorithm is higher than that of

random drawing. Moreover, it is found in Figure 4 that running time of fish swarm algorithm is also better than that of random drawing.

7 Conclusions

Fish swarm algorithm was applied to make optimization solution for test paper composition. Simulation result showed that fish swarm algorithm was better than random drawing in both composition accuracy and running time. The effectiveness and superiority of algorithm in this work, therefore, were verified.

Abstract

Community structure has been proven to have great impact on epidemic spread in weighted networks. To understand the epidemic propagation in weighted homogeneous networks with community structure, a model of pseudo-random network is presented with adjustable community structure. By changing the number of edges connecting to the nodes in the same community and the weight of edges connecting to the nodes in the same community, we investigate the epidemic spreading in weighted homogeneous networks with different community structure. Simulations show that both the number of within-community edge and the weight of within-community edge have great impact on epidemic spreading behaviour.

Keywords: epidemic spread, weighted network, homogeneous network, community structure

1 Introduction

In the past few years, the study of complex network has attracted the increasing interest since the small-world phenomenon introduced by Watts and Strogatz [1] and the scale-free phenomenon proposed by Barabási and Albert [2]. The ultimate goal of these studies on topology is to understand and explain the dynamic process up these networks, for instance, to understand how the topology of social network affects large-scale epidemics such as H1N1 [3] and so on. It is of great importance to control the epidemic spreading taking place in real world networks. A great deal of models has been proposed to investigate the feature of epidemic spreading where the node is classified in three states: susceptible (which will not infect others but may be infected), infected (which is infective) and recovered (which has recovered from the disease and has immunity). The SI [4-6], SIS [7-9], and SIR [10-12] models are proposed based on the discrete states of the nodes. To investigate the dynamical behaviours in the very early stage of epidemic outbreaks when the effects of recovery and death can be ignored, we shall focus on the susceptible-infected (SI) model in which individuals can be in two discrete states, either susceptible or infected. Each individual is represented by a node of the network and the edges are the links between individuals along which the infection may spread. An infected node can infect any of its neighbourhood nodes with a fixed probability λ at each time step and the infected nodes remain always infective. At the beginning time, I_0 nodes are randomly selected to infect the rest of the network, the dynamical process being affected by the topology of the network. The behaviours of the SI model are not only of theoretical interest, but also of practical significance.

The previous studies on networks have been principally focused on the unweighted network where edges between nodes are either present or not. However, lots of real world systems such as the scientific collaboration networks [13], the world-wide airport network [14], the mobile networks [15] and the Internet [16] have proved to be specified not only by the topology but also by the edge weight.

Accompany with the continuing study of complex networks, another common feature of many real world systems, the community structure, is founded [17-21]. Community structure is the tendency for nodes to divide into subsets within which node-node connections are dense, but between which connections are sparser. There have also been some studies to investigate the impact of community structure upon epidemic spreading in scale-free networks [22-24].

However, there are few studies to combine weight and community structure well to investigate the epidemic spreading in homogeneous networks. Indeed, the weight distribution of the edges would impact the community structure and the epidemic spreading in weighted homogeneous networks with community structure. In this paper, we proposed a model of pseudo-random network with adjustable community structure. By changing the number of edges connecting to the nodes in the same community and the within-community edge weight in the same community, we investigate the epidemic spreading in weighted homogeneous networks with different community structure.

**Corresponding author* e-mail: changzn@jit.edu.cn

This paper is organized as follows. In section 2 we describe the models, followed by the experimental evaluations in section 3. The conclusions are given in section 4.

2 Models

In order to study the dynamical behaviours in the very early state of epidemic outbreaks, we focus on the traditional SI model in which nodes are either susceptible or infected. If $s(t)$ and $i(t)$ are the density of susceptible and infected nodes at time t respectively, then $s(t)+i(t)=1$. Denote the spreading rate as λ at which each susceptible node acquires infection from an infected neighbour during one time step. In homogeneous networks, each node has approximately the same degree which makes it possible to use mean-field theory to obtain approximate results. In this case the system, we have

$$\frac{di(t)}{dt} = \lambda < k > i(t)[1-i(t)]. \tag{1}$$

Equation (1) states that the growth rate of infected nodes is proportional to the spreading rate λ, the density of susceptible nodes that may become infected $s(t)=1-i(t)$, and the number of infected nodes in contact with any susceptible one. The homogeneous mixing hypothesis considers that the last term is the product of node degree $<k>$ and the average density of infected nodes $i(t)$.

For our weighted SI model, We assume that transmit probability through the edge with weight w, λ_w, is equivalent to the infected probability that w infected nodes simultaneously influence the susceptible nodes [25,26], which is

$$\lambda_w = 1-(1-\lambda)^w. \tag{2}$$

We also employ the pseudo-random network model to investigate the epidemic spreading since all other properties such as average node degree will be equivalent to fully random networks except the controllable varying strength of community structure. These networks are comprised of n nodes which are split into *mods* communities of *n/mods* nodes each. Each node has on average Z_{in} edges connecting it to nodes of the same community and Z_{out} edges to nodes of other communities. While Z_{in} is varied, the value of Z_{out} is chosen to keep the total average degree constant, and set to $<k>$. And we assign different weights to the different kinds of edges: between-community edges are given a fixed weight of w_{out} (which is often set to 1 for simplicity), while within-community edges are given the weight $w_{in}=w$. As Z_{in} and w are increasing, the communities become better defined and easier to identify.

To know the influence of the accuracy of community structure identification on information transfer capacity, we employ the modularity measure. $\mathbf{A}$ is the adjacency matrix where $\mathbf{A}_{ij}=1$ if nodes i and j are connected and 0 otherwise. Let c_i be the community, which node i belongs to. The modularity measure, Q, is defined as follows [18]:

$$Q = \frac{1}{2m}\sum_{ij}\left[A_{ij} - \frac{k_i \cdot k_j}{2m}\right]\delta(c_i, c_j), \tag{3}$$

where $m = \frac{1}{2}\sum_{ij} A_{ij}$ is the number of edges in the network, $\delta(u,v)$ is 1, if $u=v$ and 0 otherwise. The higher the modularity Q_{max} is the stronger community structure the network has. In practice values for such networks typically fall in the range from about 0.3 to 0.7. Higher modularity values are very rare.

3 Simulations and analysis

At first, we check the impact of within-community edge weight w on the maximum modularity Q_{max} using pseudo-random networks with n=128 nodes which are divided into *mods*=4 communities with 32 nodes in each community. The average degree $<k>$ is set to 16. Simulation results are shown in Figure 1.

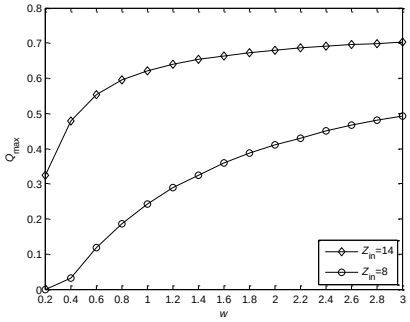

FIGURE 1 Q_{max} vs w, n=128, *mods*=4, $<k>$=16

From Figure 1 we can obtain that the increasing of edge weight will result in the increase of community structure especially in the traditional random network. In the pseudo-random network which has more with-community edges (Z_{in}=14 in Figure 1), the network has pronounced community structure even though the within-community edge weight is smaller. And the greater the number or the weight of within-community edge is, the higher the maximum modularity Q_{max} is.

Then we check the impact of the number of within-community edge Z_{in} on the maximum modularity Q_{max}. Simulation results are shown in Figure 2.

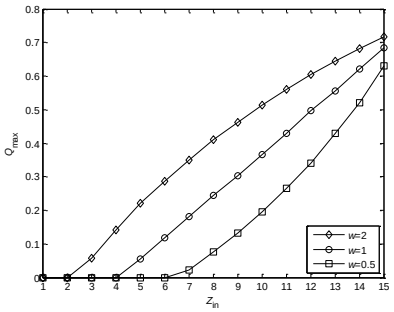

FIGURE 2 Q_{max} vs Z_{in}, n=128, *mods*=4, $<k>$=16

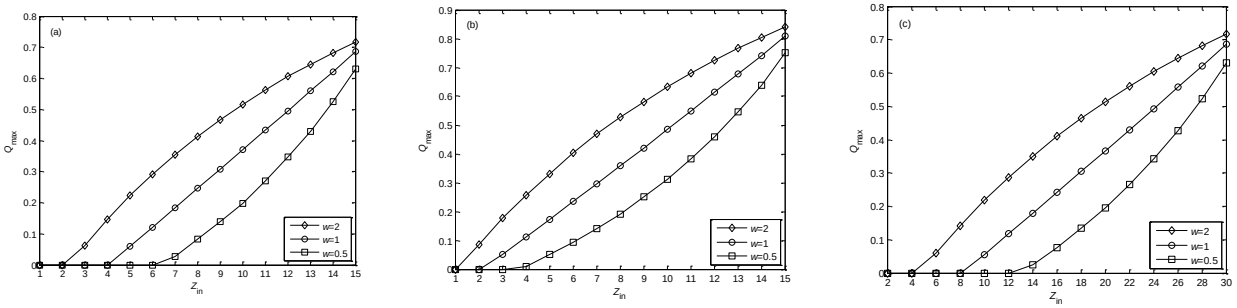
Figure 2 also proves that the greater the number or the weight of within-community edge is, the higher the maximum modularity Q_{max} is.

Then we check the impact of the total node number n, the community number *mods*, and the average node degree $<k>$ on the maximum modularity Q_{max}. Simulation results are shown in Figure 3.

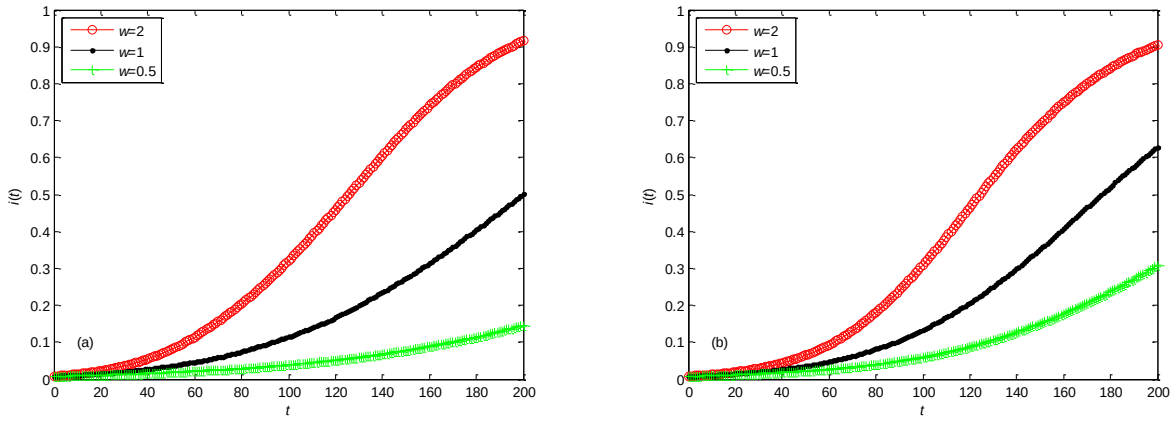


a) n=256, *mods*=4, $<k>$=16 b) n=128, *mods*=8, $<k>$=16 c) n=128, *mods*=4, $<k>$=32

FIGURE 3 Q_{max} vs Z_{in}

Comparing with Figure 2, we double the total node number, the community number and the average node degree to get the results shown in Figure 3a, 3b and 3c correspondingly. From Figure 3 we can obtain that the maximum modularity Q_{max} is also increasing accompany with the number and the weight of within-community edge. Only the changing of the community number affects the absolute value of maximum modularity. The changing of the total node number and the average node degree will barely affect the result of maximum modularity.

Now we focus on the epidemic spreading in weighted homogeneous networks. We set the the number of within-community edge Z_{in} as 14 for the network which has stronger community structure and 8 for the network which is a traditional random network. (In the scenario where average degree is 32, it changes to 28 and 16 accordingly.) At the initial age, we select a node randomly and make it an infected node. At each time step, the infected nodes will interact with their neighbours with probability λ_w which is defined in Equation (2). Simulations of different scenarios are shown in Figures 4, 5, 6 and 7.

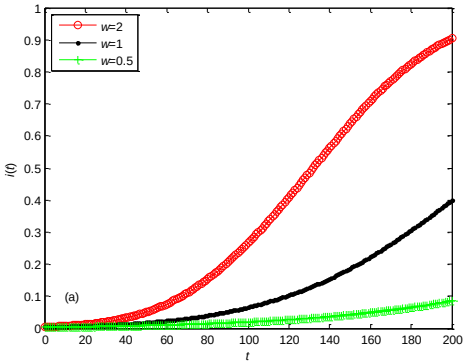


a) Z_{in}=14 b) Z_{in}=8

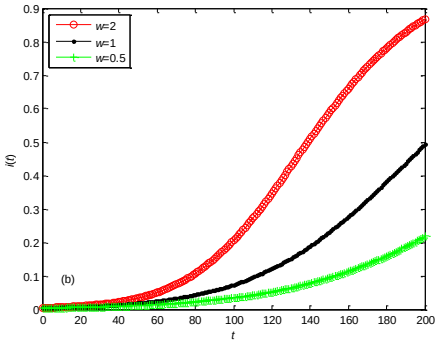
FIGURE 4 Epidemic spreading in weighted networks, n=128, *mods*=4, λ=0.002, $<k>$=16

In Figure 4, we report the density of infected nodes versus time in weighted homogeneous networks with different community structure. As shown in each figure, the epidemic propagation velocity is higher in networks with greater weight of within-community edge. However, when the weight of within-community edge is less than the weight of the between-community edge (w=0.5), less within-community edge will unexpectedly accelerate the epidemic propagation.

Then we also double the total node number, the community number and the average node degree to get the results shown in Figures 5, 6 and 7 correspondingly.

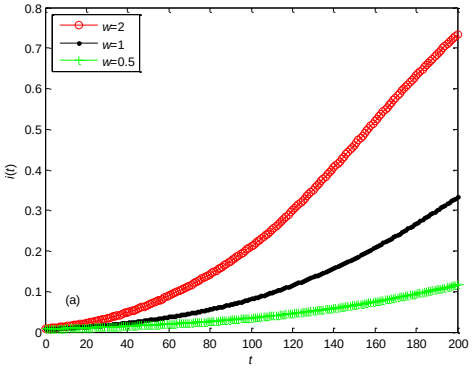


a) Z_{in}=14

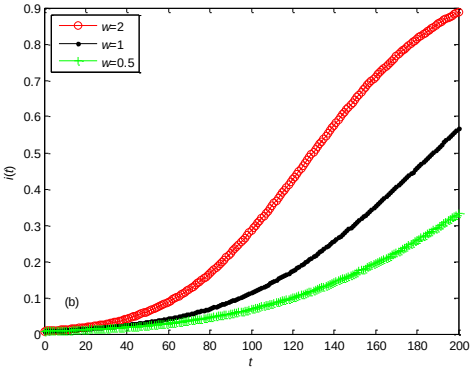


b) Z_{in}=8

FIGURE 5 Epidemic spreading in weighted networks, n=256, *mods*=4, λ=0.002, <k>=16

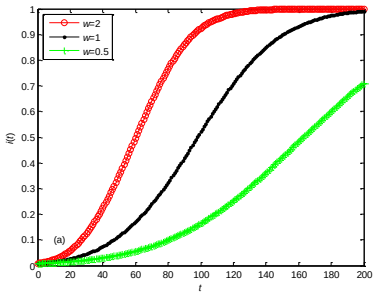


a) Z_{in}=14

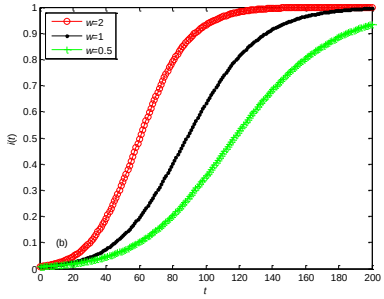


b) Z_{in}=8

FIGURE 6 Epidemic spreading in weighted networks, n=128, *mods*=8, λ=0.002, <k>=16



a) $3Z_{in}$=28

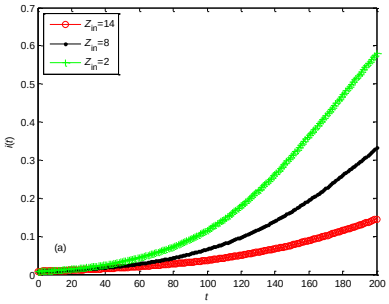


b) Z_{in}=16

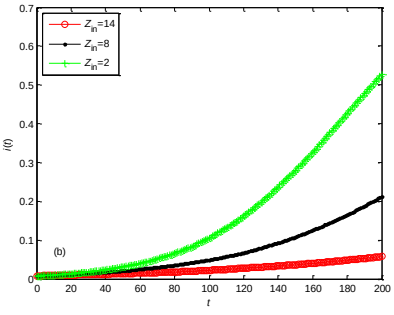
FIGURE 7 Epidemic spreading in weighted networks, n=128, *mods*=4, λ=0.002, <k>=32

As shown in each Figure, the increasing of weight of within-community edge will result in the acceleration of the epidemic propagation and less within-community edge will also accelerate the epidemic propagation when the weight of within-community edge is less than the weight of the between-community edge.

We utilize different within-community edge number Z_{in} to check the impact on epidemic spreading as shown in Figure 8.



a) w=0.5



b) w=0.25

FIGURE 8 Epidemic spreading in weighted networks, n=128, *mods*=4, λ=0.002, <k>=16

In both scenarios where the weight of within-community edge is less than the weight of the between-community edge, less within-community edge can accelerate the epidemic propagation.

4 Conclusions

How the community structure impact on the epidemic spreading in weighted homogeneous networks is studied in this paper. With our weighted SI model and the computer-generated pseudo-random networks model, the epidemic propagation velocity is studied in difference scenarios. Both increasing the number of within-community edge and increasing the weight of within-community edge can enhance the community structure. And increasing the weight of within-community edge will result in the acceleration of the epidemic propagation. Furthermore, we also proposed that less within-community edge will accelerate the epidemic propagation when the weight of within-community edge is less than the weight of the between-community edge. This study will shed light on how to restrain the epidemic spreading in weighted homogeneous network.

Abstract

Embarking from road's characteristic and road design's demand to the simulation system, road simulation system's characteristics have been discussed, and then road simulation system frame based on multi-agent has been constructed. The simulation agents have been divided into response agent, corporation agent and interface agent, and their structures have been analysed too. The car dynamics model, road ground view model and driver model have been built, the simulation results are validated by basic experiments. The simulation system is an efficient tool for road design evaluation.

Keywords: road simulation, road engineering, multi-agent, simulation model

1 Introduction

Road engineering investment is huge; it is not possible to verify rationality of design program through making "sample". Design is influenced by many factors; it is difficult to use a mathematical model to evaluate. Because of the lack of enough information, experts can only rely on experience to judge, it is difficult to make an objective and comprehensive evaluation [1]. The computer simulation technology is introduced into the evaluation of road design, through studying and establishing the road simulation system, takes the road geometry linear as the main body, repeatedly carries on the simulation experiment to the road design plan, scientific analysis and evaluation of the simulation results, may achieve the purpose of scientific evaluation of road design program.

The road simulation system is continuous variable dynamic system (CVDS) and discrete event dynamic system (DEDS) interaction promiscuous system (HS), has complexity, hybridity, interactivity, timeliness and modularity and other characteristics [2]. Therefore, in the road simulation system, how to describe the interaction of the discrete event and continuous variable, portray promiscuous system behaviour essence of road, so coordinate news transmissions of among various agent based on DEDS and CVDS in the process of simulation, is one of the key of simulation system [3].

Under these guides, the characteristics of road simulation system, system framework and development method are studied in this paper, which lays a theoretical foundation for the development of the simulation system, and has an important significance to realize signification, visualization, intelligent of road design.

2 Characteristics and framework of road simulation

2.1 ANALYSIS OF ROAD SIMULATION SYSTEM'S CHARACTERISTICS

Time-variable characteristic in road simulation process may describes with the following the time-variable characteristic model of person, car, road and environment.

$$\begin{cases} \Phi(t_i) = \{\alpha^i, r^i, w^i\} \\ \alpha^i = \{\alpha_v^i, \alpha_{av}^i, \alpha_{aH}^i, \alpha_\beta^i, \alpha_o^i, \alpha_p^i\} \\ r^i = \{r_H^i, r_V^i, r_C^i\} \\ w^i = \{w_E^i, w_C\} \end{cases}, \quad (1)$$

where $\Phi(t_i)$ is the time-variable characteristic model of person, car, road and environment. α^i is car's condition at t_i moment. $\alpha_v^i, \alpha_{av}^i, \alpha_{aH}^i, \alpha_\beta^i, \alpha_o^i, \alpha_p^i$ are car speed, longitudinal acceleration, lateral acceleration, front wheel corners, car conditions as well as positions describes respectively at t_i moment. r^i is road geometrical characteristic at t_i moment. r_H^i, r_V^i, r_C^i are road's horizontal, vertical and Cross-section geometric characteristics respectively at t_i moment. w^i is surrounding environment characteristic at t_i moment. w_E^i is environment characteristic at t_i moment. w_c expresses weather characteristic [4, 5].

With $Q_{i+1}(\Phi(t_{i+1}))$ described transport condition that is determined by environmental information at t_{i+1} moment:

$$Q_{i+1}(\Phi(t_{i+1})) = p_i(Q_i(\Phi(t_i))), \quad (2)$$

* ***Corresponding author*** e-mail: hushengneng2006@126.com

where p_i is an operator that has function to car, and non-correlated with road or environment, namely driver's operation to car. Type (2) also explained the transport condition $Q_{i+1}\left(\Phi\left(t_{i+1}\right)\right)$ that the process expected may achieves the travel goal, through adjusting process characteristic parameter α_i.

The above time-variable characteristic mode reveals, road simulation system has the following features:

1) Continued corresponding feedback character, the road simulation experiment advances continually along with extending of route. In this process, the driver model car model and road virtual environment model has the characteristic of persistent response.

2) Intelligent simulation characteristic, the road simulation system's pilot controls behavior is one kind of intelligent decision behavior, pilot model in the simulation system should have the auto-adapted characteristic, along with the change of person, car, road and environment time-variable condition, pilot model automatic adjust its control policy.

3) Hybridity, the road simulation system is promiscuous system that is unified of road and environment characteristic's discrete state, pilot manipulative separate behavior and car operational continual condition. The evolution of system is driven by the time (car movement) and event (pilot operation, road and environment state event) the two different mechanism, displays for the structure, algorithm hybridity.

2.2 MULTI-AGENT SYSTEM THEORY

Agent is a software entity that can realize the function under the specific environment continuously and spontaneously, and associates with the relevant agent and process. Continuous and spontaneous request originates from the change of environment, requests agent to real-time respond to user demand under nobody guides and interference by flexible, intelligent way. In addition, there is also hope that the agent could communicate and cooperate with other agent in the environment and the process [6].

The multi-agent system needs realizes with the aid of some correlation theories and technologies, mainly includes the knowledge expression and inference, agent communication language, multi-agent coordinates model, multi-agent to consult model:

1) Knowledge expression and inference. If a single agent in the system through a certain data structure and the corresponding operation to address the problem of modeling, must use the knowledge expression and inference method correlation theories.

2) Agent communication language. Communication and information exchange between agents need to a certain level of agreement as a basis, agent communication language can be used to accomplish this function.

3) Multi-agent coordinates model. In the multi-agent system category, reciprocity needs to be coordinated between agents. Coordination model is to provide a formal framework for the interaction among agent multi-agent coordination model can be divided into control actuation and data driven two types.

4) Multi-agent negotiation model. The multi-agent system is a system composed of a plurality of agent, which can solve the complex problem which single agent cannot solve, question solution network are formed by many agent coordinated cooperation. In multi-agent system, cooperation between agents is to be done through communication and consultation. Regarding multi-agent system model, has the different viewpoint, generally thinks that agent should include sensors, decision controller, mental state, knowledge base, communicator etc. several parts of compositions, Including the BDI model is a widely accepted model of agent negotiation model, it reveals the agent energetic factor including belief, desire, intention etc., as shown in Figure 1.

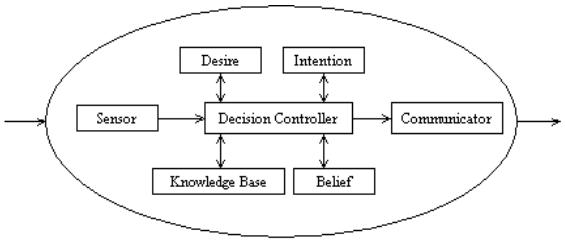

FIGURE 1 BDI model

2.3 DEFINITION OF ELEMENTAL AGENT

In order to facilitate the formal description of Agent, commonness of agent system can be abstracted, is defined as elemental agent. According to the characteristics of agent in the road simulation system and refers to the agent dynamics characteristic, defines agent as:

$$\begin{aligned} &Agent = \left\langle A \cdot id, T, I, O, S, IA, OA, R \right\rangle \\ &T \in R_0^+ \\ &I = EI \bigcup II \\ &\forall_i \in I^{\Rightarrow} i \cdot source \in IA \\ &\forall_o \in O^{\Rightarrow} o \cdot source \in OA \end{aligned} \quad ,$$

where $A \cdot id$ is identifier for the Agent. T is a logical clock. I, O are respectively for the input and output messages. EI is the external input news, II for internal input news. S is state set of elemental agent, the status in S is the limited dimensions real number vector. IA is all of the agent set that is possible to input message for this Agent. OA is all of the agent set that is possible to output message for this Agent. R is rule processing of elemental agent.

The message and the message flow in agent can be defined, according to the BNF form, the message is defined as:

*<system message>::=<message ID><message type>(:<parameters>)**

<*message ID*>::=<*digital*>*
<*message type*>::=<*identifier*>*
<*parameters*>::=<*parameter name*><*blank*>(:<*parameter value*>)*
<*parameter name*>::=<*identifier*>
<*parameter value*>::=<*identifier*>
<*identifier* >::=<*letter*>(<*letter*>|<*digutal*>|_)*
While the message flow can be defined as:
<*system message flow*>::=<*message flow aim*>
<*message flow source*>
<*send time*><*effective time*>
<*message format*><*system message*>

The status (*S*) of agent can be described by five vectors:

$$S = \langle A \cdot id, EI \cdot n, A \cdot e, EO \cdot n, t \rangle .$$

Type: $A \cdot id$ is identifier for the Agent; $EI \cdot n$ is name of input event for agent; $A \cdot e$ is activation state of agent; $EO \cdot n$ is name of output event for agent; t is the running time of agent after activation.

2.4 SIMULATION SYSTEM FRAME FOUND ON MULTI-AGENT

The above characteristic of road simulation system determines the software development method of traditional which is oriented to process oriented and object, is hard to process under the time-variable condition among the subsystems alternately, coordination, auto-adapted, self-feedback and other characteristics, simultaneously is also hard to solve the road simulation system hybridity problem. Statement of multi-agent system software development thought that to solve the software intelligence and cooperation has provided a new way.

According to person, car, road and environment simulation system's time-variable dynamic characteristic, the person, car, road and environment simulation system frame based on multi-agent as shown in Figure 2.

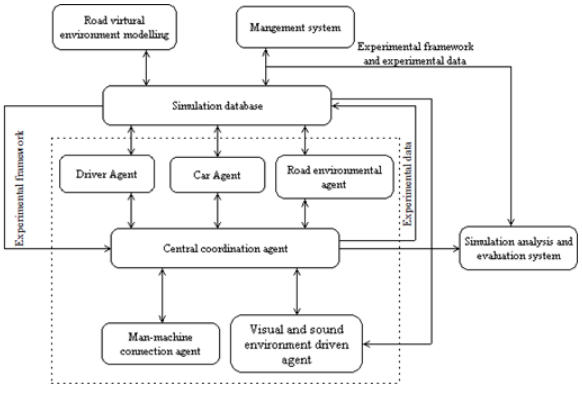

FIGURE 2 Person, car, road and environment simulation framework based on multi-agent

Here human, car, road and environment simulation system is composed of 6 interactions of agent, according to its duty and the difference of solution mechanism undertaking to duty, may be divided to respond agent, cooperation agent and interface agent 3 kinds. Driver agent, car agent and center coordinate agent to belong to cooperation agent, namely has internal behavior initiative agent, has knowledge representation, question solution expressed and so on. Road environmental agent and visual-audio driver agent belong to respond agent, but simply has the response to the exterior stimulation simply, is similar to customer/server architecture, agent is not only the customer, is the server, according to the procedure arrangement, makes to reply or send out the request. Man-machine connection agent belongs to interface Agent, can interactive with the user, carries on display and control [7].

In the road simulation system, various agent characteristics are different, its basic structure is also different, this article only describes the basic structure of central coordination agent, the center coordinates agent is at the core position in the multi-agent system, is responsible for message distribution, coordination, simulation clock coordination, its basic structure as shown in Figure 3.

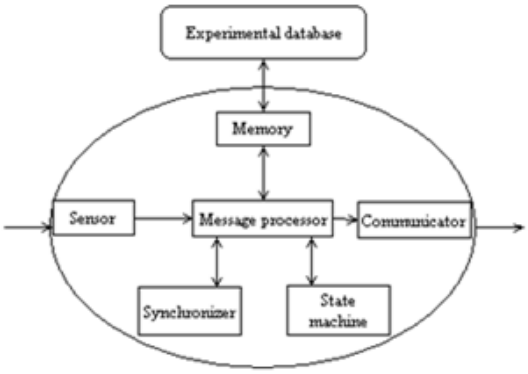

FIGURE 3 Center coordinates agent

Here the sensor is responsible for the receive of environmental information, distribute news through message processor to memory, synchronizer and state machine, the memory and experimental analysis, evaluation of relevant information store in the experiment database. The message processor has a message distribution function and agent internal state storage and adjustment function. The state machine memory system's time-variable environmental information, and distribute the previous time-variable environmental information by the message processor to the synchronize hand-in-hand processing row state renewal [8]. The synchronizer according to the definite rule, decided the message that in advance must distribute, uses the message processor and communicator distribution to other agent. For example, when central synchronizer receives driver agent operation information, the synchronizer compares the information with the information that state machine save, if there is no change, the information will no longer be distributed to the car agent, otherwise, then transmits [9].

3 Establishment of Road Simulation Model

3.1 CAR MULTI-BODY DYNAMICS SIMULATION MODEL

Traditional analyses of road alignment index is usually based on the classic car dynamic model, regards car as a particle, neglects various car part of relations, but does not tally with the reality. The car dynamics model established in this paper is based on multi-body dynamics system. In order to facilitate the modelling and the mathematical expression, simultaneously took into consideration the road simulation systems characteristic, has carried on the following simplification to the automotive system:

1) The car, frame and packing container as an object to be processed.

2) The front axle and rear axle of car may reciprocate to the car body and rotate around the longitudinal axis parallel to the axis of the car, around the shock absorber is simplified as a damping restraint, the frame and axles are connected by leaf springs and shock absorbers.

3) Steering system the steering wheel and column can be simplified to rotate objects around the car body, the steering unit is only considered that rotates around the body of the axle, the steering column and between steering units' axes with the universal joint.

4) The tire model uses the FIALA tire model.

3.2 DRIVER MODEL BASED ON PREVIEW THEORY

The car presents time-variable dynamic road environment to the driver in the process of travel, and the driving behavior the effect on the car displays for the driver to take operation behavior after the environment sensation. The basic principle of the driver control car is to cause car's movement as far as possible consistent with expected trajectory and speed. Therefore, according to person's behavior stimulation- organism - response classic mode, driving behavior can be divided into 3 stages, namely information sensation, judgment decision-making and operation adjustment. As shown in Figure 4:

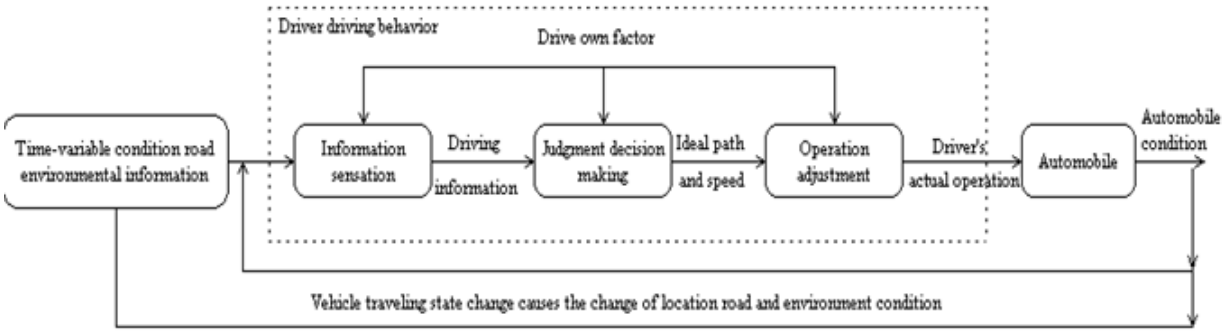

FIGURE 4 Driver operation behaviour flow char

3.3 ROAD SCENE MODEL BASED ON CONSTRAINED DELAUNAY TRIANGULATION

The request of road ground view model is expressed by the different resolution through constraint dlaunay triangulation (CDT), modelling plan of this system is used for road simulation model based on CDT, and the modelling process is described as follows:

1) Carries on the pretreatment to the topographical data, first carries on the data filters, the rejection wrong spot and closely coincide, next data grid, to enhance data retrieval speed.

2) Using the point by point insertion algorithm, establishes the basic Delaney triangulation.

3) Using "wears hat" principle of road cross-sectional design, obtains the intersection of road side slope and triangular net, forms the closed polygon.

4) Using the CDT algorithm, the closed polygon according to the line segment is inserted into the basic triangle net, forms the constrained Delaney triangulation.

5) Using triangular net virus algorithm, rejection closed polygon interior triangular net.

6) Using point by point insertion algorithm, builds the road three-dimensional model, the road three-dimensional odel and topographical model superimposition, forms ground view simulation model - line frame model.

7) Based on edge collapse algorithm,

Multi-level detail model of ground view simulation model has been built.

8) Enduing the model material and texture, finally builds the ground view simulation model.

4 Simulation Model Confirmations

Simulation model is set up for simulation experiments, to reveal the behaviour characteristics of the original system by simulation experiment. However, it is not possible to confirm whether a model is effective well at a modelling. When the system is quite huge and complex, in order not to make the cost of model establishing and running is too high, the complexity of the model is limited, has to make some assumptions or simplified, so it is necessary to verify the effectiveness of the model. Key field tests were conducted on vehicle dynamics. In model validation, using the method based on experimental data, in the same boundary condition and scene consistent situation, compared with actual experimental data simulation experiment data, the model was modified according to the comparison result.

4.1 EXPERIMENTAL DESIGN

Experimental road section is Dian Liang – Cai Guan Ling section of Bao Ji – Han Zhong road in China's Shanxi province. This road is second-class road of mountainous hilly area, design speed 40 km/h, asphalt pavement width 7 m, roadbed width 8.5 m. Region's altitude of the route is at 1 200m~1 350m, by the topographical constraint, this road section consecutively 5 km downhill, plane indices except sight distance of individual curves cannot meet the requirements, other indices conform to the standard stipulation.

Experiment vehicles and instrument: Test vehicle uses YaXin JS6820C32D1, maximum speed 110 km/h, carrying capacity 5 t; the car speed uses the fifth wheel instrument real-time collection and record.

4.2 SIMULATION EXPERIMENTAL PLAN

According to the uphill and downhill two cases are considered, in the downhill experiment the car is pressed 30,40,50 km/h to hang 3 grades of glides by the top of slope to the base of slope, in the glide process, loosens the accelerator pedal. In the uphill experiment the car is pressed 40, 50, 60 km/h to hang 3 grade and accelerator full hill climbing to go by the base of slope. In the simulation, road model is established according to the actual road, the car simulation model is built, which is consistent with 5 t experimental cars.

4.3 RESULT ANALYSIS

Figure 5 is the field test data and model test data of car with 50 km/h from top hanging 3 archives to glide. The test section longitudinal slope of 7%, there are two horizontal curve, radius is larger than 200m, In the simulation model, friction coefficient between tire and road surface takes 0.65, indicates that the simulated data and empirical datum have certain error, The error is mainly from the following two aspects: First, in simulation testing the road surface friction coefficient value and actual situation have the difference. This experimental road section puts into use for many years later, the different sector road surface attrition and destruction condition are different, cause the road surface friction coefficient to be different; Second, the local transportation department responsible for the work to prevent the vehicles exceeds the speed limit, has established the caution belt in the steep slope road section, has certain influence to the field test data. Even so, Figure 5 shows the simulation results and experimental data are in good agreement and the error is in the allowable range, so test data of 40 km/h and 30 km/h. therefore the simulation model is effective. In the later design proposal appraisal experiment, only need change parameter of path model, but does not transform the car model, may carry on to analyse and study to various parameters in road route design.

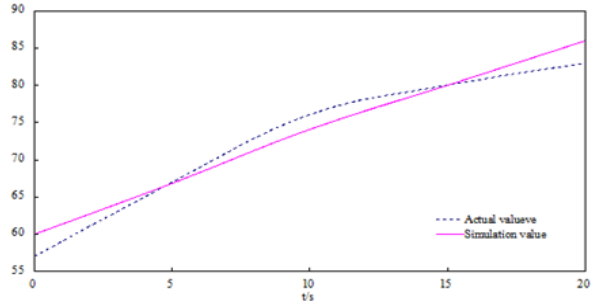

FIGURE 5 Actual data and simulated data contrast

5 Conclusions

The road simulation system has been established to evaluate the road design, on the basis of the analysis simulation characteristic, development and framework of road simulation system have been proposed, agents of road simulation have been defined, the center coordinates agent and driver agent have been discussed, and this system is confirmed through the project example, an important guiding significance for the development of road simulation system has been provided.

Acknowledgments

The research project was funded by a grant from the Ministry of Transport of China. The authors gratefully thank my professional brothers at Chang'an University in Xi'an. Finally, we would like to express our gratitude to the study subjects who uncomplainingly underwent the rather demanding trials.

Abstract

Proposed an improved DV-Hop localization algorithm (PLS-DVHop) based on partial least squares, which uses the partial least squares to model of hop-count and the Euclidean distances, along with the maximum covariance of input matrix and output matrix to estimate the location of unknown nodes. PLS-DVHop has strong adaptability for different deployment network, and overcomes the shortage of only suitable for isotropic networks in the original algorithm. Simulation results show that PLS-DVHop algorithm has high estimate precision and stable performance, can adapt to different network topologies, and is very suitable for large scale deployment network.

Keywords: range-free localization, wireless sensor network, partial least squares

1 Introduction

Wireless sensor network (WSN) [1, 2] is constituted in ways of self-organization and multi-hop by large volumes of sensor nodes with communication and computation capability. Nodes in the network are able to collaboratively perceive, collect, process, and transmit the information of perceived objects within the coverage area of the network, as well as to report the information to users. WSN has great potential application value in military, transportation, medical care, and environment monitoring [1]. Location estimation is a key issue for WSN [3, 4]. Different from traditional networks, WSN is a data-based network. Thus, in WSN localization researches, statistics and multivariate analysis methods are often applied for quantitative analysis.

In the application of WSN, nodes' location information can be acquired by adding global position system (GPS)/BeiDou Navigation Satellite System (BDS) devices on nodes. However, this way is only applicable with outdoor. Besides, GPS/BDS device is large in volume, and high in cost and energy consumption. Moreover, GPS/BDS device also needs stable base installations. These facts have made it difficult to realize the requirements of WSN, which is "low price, low cost and low energy consumption" [5]. As for this, in practice, only some of the nodes can be installed with GPS/BDS device. For the rest nodes, their location information can only be estimated via a certain algorithm or method. After several years' development, researchers have proposed many node localization approaches. According to whether the range information is used among the localization process, the localization techniques can be classified into range-based and range-free [3, 4, 6]. The range-based method exploits distance or angle information between neighbour nodes, and then uses the information to localize nodes. The range-based localization has higher location accuracy but requires additional hardware support and thus, is very expensive to be used in large scale sensor network. The range-free localization is being considered as a cost-effective alternative to range-based methods because of hardware limitation in large scale deployment. On the other hand, range-free schemes do not need additional hardware support and makes use of connectivity, multi-hop routing and other information between nodes to estimate nodes location. Therefore, range-free technique is considered to be most effective solution for the localization issues in WSN.

The DV-Hop localization algorithm proposed by Dragos Niculescuet et al. [7, 8] from Rutgers University is one of a series of distributed localization algorithms, it is a localization algorithm not related to the distance, it smartly uses the distance vector routing and the idea of GPS localization, and this algorithm has great distributive and expandability. DV-Hop method is an ideology based on distance vector routing and GPS, which makes use of hop distance to replace real distance between nodes. Eventually, least squares are applied to estimate the position. DV-hop algorithm assumes that the network is isotropic and uniformly distributed, that is, when the properties of the graph are the same in all directions, so that the corrections that are deployed reasonably estimate the distances between hops. Unfortunately, in practice, networks may be anisotropic and may contain com plex inner or outer boundaries, which make the least hop counts deviating the Euclidean distances. This paper integrates PLS in multivariate analysis, making use of the correlation between hop-counts and Euclidean distances between known nodes to establish an optimal linear conversion matrix. On this basis, the matrix is used to convert hop-

counts between unknown nodes and known nodes into distance, so as to realize compensation on distance estimation in networks with unevenly distributed nodes, reaching the effect of high localization accuracy.

2 Related works

In recent years, it has become a new research hot spot to make use of multivariate analysis technique in modelling and algorithm design of localization mechanism [9, 10]. The method puts to use the relation between distribution feature and measurement information of known nodes to establish a mapping function. On this basis, the function will be used to estimate the location of unknown nodes. Compared with previous methods, multivariate analysis is able to effectively discover network topology, correlation and other information hidden behind data. Lim et al. [11] proposed a PDM (Proximity Distance Map) algorithm based on TSVD (Truncated Singular Value Decomposition) technique. PDM describes the optimal linear transformations between the hop-count and the Euclidean distances under the least-squares metric. With the help of PDM, an unknown node is able to obtain more accurate distance translation, thus to get a better location estimation. Firstly, the PDM method uses matrices to express the collected Euclidean distances and the hop-count between known nodes; secondly, TSVD technique is used to conduct linear transformation of two matrices to obtain an optimum linear transformation model; lastly, the hop-counts from the unknown nodes to the known nodes will be applied to this model to estimate the Euclidean distances between the unknown nodes and the known node. In essence, TSVD [12] is a multivariable linear regularization learning method, the estimated Euclidean distances obtained through method is actually the weighted sum of the estimated values of other known nodes in the monitoring area, and therefore, the obtained estimated value is close to the actual value. In addition, the TSVD method has abandoned the small singular values, which can to a certain extent reduce the impact of noise during the transformation process, so the collinearity problem during the localization process can be avoided, and the stability of algorithm can be increased. All these have caused the algorithm to have a low requirement for the deployment of sensor nodes, connection and signal attenuation method, which more benefits its use in complex application environments. In a certain degree, TSVD can solve some problems of range-free method, but the literature and experiment show that the PDM method only works under certain conditions, and when the beacon nodes are sparse or various radio ranges have serious anisotropy, the performance of TSVD method will sharply decrease. The main drawback of PDM is that it need to set a threshold parameter k. TSVD technique directly sets the singular values smaller than the threshold parameter k as zero, and if k is properly chosen, the solution of TSVD is stable, otherwise, it will reduce the algorithm's performance. Moreover, the PDM method has not conducted standard processing to the hop-counts and Euclidean distances, and different dimensions have caused a certain degree of data submergence. In addition, TSVD modelling only takes into consideration hop-counts information, disregarding Euclidean distance information. As for this, the model built is unable to truly reflect the relationship between hop-counts and real distance. Inspired by PDM method, Lee et al. [13, 14] put forward SVR-based localization method – LSVR (Localization through Support Vector Regression). The localization method is fit for different networking environment. Moreover, under small sample condition, it still leads to good positioning accuracy. However, LSVR is a multi-input and single-output algorithm [15]. In practical localization practices, modelling is to be performed frequently, sharply increasing the complexity of the algorithm. Moreover, with the number of beacons increases, time and space resource required by positioning will grow geometrically.

In order to reduce the complexity of localization problem, to improve the generalization performance of positioning method, and to simplify localization model, it is quite necessary to perform feature extraction before model building. Researchers have found that, PLS (Partial Least Squares) [16, 17] is able to perfectly realize feature extraction from input to output. PLS is a standard multivariate regression method, which is to form components that capture most of the information in the explanatory variables that is useful for predicting dependent variables, while reducing the dimensionality of the regression problem by using fewer components than the number of explanatory variables. PLS technique is considered especially useful for constructing prediction equations when there are many explanatory variables, comparatively little sample data and the collinearity between independent variables. It also has strong anti-noise property and great generalization ability, it does not require obtaining the distribution model of the sample in advance, and it also has various characteristics such as a high predication precision, so it is also called the second-generation regression method. Inspired by the PLS and based on DV-Hop localization method, the paper makes use of PLS technique in multivariate regression to optimize DV-Hop algorithm, and proposes a PLS-based DV-Hop localization method (PLS-DVHop).

3 Brief Reviews of DV-Hop, PLS

Before the introduction of our algorithm, for completeness, we will briefly review DV-Hop and PLS in the next sub-sections.

3.1 DV-HOP

DV-Hop method does not require any hardware to measure ranges or angles to neighbours. It only relies on the connectivity of the underlying graph and it comprises three no overlapping stages:

1) First, each node estimates the least hop-counts to each beacon and maintains a table $[x_i, y_i, h_i]$ and exchanges updates only with its neighbours. Where $[x_i, y_i]^T$ denotes the physical location of beacon i, h_i is a counter to record the hop-counts to beacon. This phase is the classical Bellman-Ford distributed shortest path algorithm.

2) In the second stage, beacons cooperatively estimate the average distance of each hop in the network. Once a beacon j gets the hop count h_i to beacon i, it reports the value of h_i to beacon i. After collecting these values from all other beacons, beacon i (locating at $[x_i, y_i]^T$) calculates the average distance of each hop in the network, uses it as an adjusted value and broadcasts it to the network. The average distance of each hop can be expressed by the following equation:

$$HopSize_i = \frac{\sum_{i \neq j} \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}}{\sum_{i \neq j} h_i}. \quad (1)$$

3) After receiving the correction, an arbitrary node may estimate distances to beacons. Suppose an unknown node receives the messages from three beacons, i.e. beacon i, j, and k. It uses the three distance estimates ($HopSize_i \times h_i$, $HopSize_j \times h_j$, and $HopSize_k \times h_k$) to determine its location by trilateration or maximum likelihood method.

3.2 PLS

Before regression, PLS makes use of covariance to guide feature extraction of input variable and output variable. In the process of extraction, information integration and screening technology is applied, so that PLS method overcomes correlation of input variable, eliminating the influence of co-linearity on regression. Moreover, in the process of regression, interpretation and prediction role of input on output is emphasized, which eliminates noise unfavourable to regression. As for this, PLS method leads to good robustness and prediction stability. PLS method always converts multivariate regression problem into several simple regression problems, so that it is also fit for small sample. Owing to such favourable natures, PLS is quite fit for WSN localization.

Linear PLS method comprehensively considers input variable **H** and output variable **D**, which solves component **t**, **u** (**t** is linear combination of variable **H**, and **u** is linear combination of variable **D**). The principle is shown in Figure 1:

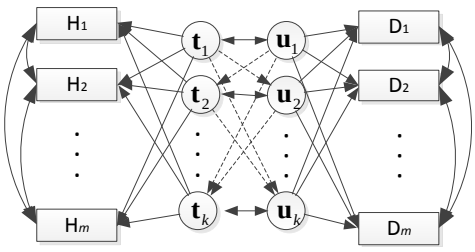

FIGURE 1 The schematic diagram of PLS

It may be seen from Figure 1 that, cross covariance between **H** and **D** is important information. Such cross covariance is hoped to be described through k. Thus, solution of PLS shall meet:

1) **t** and **u** shall try to carry variation information of their respective data sheet as much as possible.

2) The correlation between **t** and **u** may be maximized. PLS is described as solution of optimization problem:

$$\max \left\| \mathrm{cov}(\mathbf{t}, \mathbf{u}) \right\|^2 = \max[\mathbf{Hw}, \mathbf{Dc}], \quad (2)$$

where, **w**, **c** is weight vector.

Basic steps of PLS algorithm is shown below:

Firstly, input and output variables are to be standardized, so as to eliminate influence on final calculation result caused by inconsistent dimension of input and output variable;

The first principle component $\mathbf{t}_1$ and $\mathbf{u}_1$ are separately extracted from input and output variable H, D. In accordance with the demand of regression, the below conditions shall be satisfied:

- $\mathbf{t}_1$ and $\mathbf{u}_1$, shall try to carry variation information of variable **H**, **D** as much as possible;
- Correlation between $\mathbf{t}_1$ and $\mathbf{u}_1$ shall be able to be maximized.

After extraction of the first component $\mathbf{t}_1$ and $\mathbf{u}_1$, regression of **H**, **D** on $\mathbf{t}_1$ shall be separately performed. If the regression equation has reached satisfactory precision, PLS method will be terminated. Or else, residual of **H** after being interpreted by $\mathbf{t}_1$, as well as residual of **D** after being interpreted by $\mathbf{u}_1$ will be utilized to perform the second round of component extraction. Repeat the process, until a satisfactory precision is obtained.

4 The establishment of PLS-DVHop localization model

The localization process of PLS-DVHop work in two phases: offline training phase and an online localization phase. More specifically, in the offline training phase, we take two steps for model building. In the first step, we collect hop-counts and Euclidean distances between beacons as the training set. In the second step, we make use of PLS technique to obtain the mapping model between hop-counts and Euclidean distances. In the online localization phase, the real-time hop-counts samples received from the beacons by the unknown node, and then the unknown node uses the mapping model obtained through the training to conduct location estimation.

Consider a WSN which is comprised of n sensor nodes $\{S_i\}_{i=1}^n$ deployed in a 2D geographic region. Without loss of generality, let the first m nodes be beacons whose locations are known, for all $i = 1,\ldots,m$, where $m \ll n$. For every pair of sensors S_i and S_j, h_{ij} denotes shortest hop-count and d_{ij} denotes Euclidean distances that sensor S_i receives from sensor S_j. After running for a period of time, we can obtain two matrices, *i.e.*, the shortest hop-counts matrix $\mathbf{H}=[\mathbf{h}_1,\ldots,\mathbf{h}_m]$ and the Euclidean distances matrix $\mathbf{D}=[\mathbf{d}_1,\ldots,\mathbf{d}_m]$, where $\mathbf{h}_i=[h_{i1},\ldots,h_{im}]^T$, $\mathbf{d}_i=[d_{i1},\ldots,d_{im}]^T$.

Considering the relationship Euclidean distances and hop-counts, and according to the multiple regression theory. We can obtain an equation, which can be expressed as:

$$\mathbf{D} = \mathbf{H}\boldsymbol{\eta} + \boldsymbol{\varepsilon}, \tag{3}$$

where, $\boldsymbol{\eta} = (\eta_1, \eta_2, \cdots, \eta_m)^T$ is the regression coefficient vector, $\boldsymbol{\varepsilon}$ is the errors vector.

In order to minimize the error, as well as for the convenience of computation, we often use quadratic sum of error as the judgment standard. In order to figure out the optimal relation between the hop-counts and Euclidean distances, we are to figure out the partial derivative of the quadratic sum of error, and assuming that it is 0, hereby:

$$\mathbf{H}^T\mathbf{H}\hat{\boldsymbol{\eta}} = \mathbf{H}^T\mathbf{D}. \tag{4}$$

It may be seen from Equation (2) that, there may be as well multiple correlations between variables in **H**, or the number of samples in **H** may be smaller than the number of variables. If so, forced calculation of Equation (2) may leads to invalid result. In addition, the precision of estimation value $\hat{\boldsymbol{\eta}}$ is not only related with input variable, but also related with output variable **D**. Input and target co-determines the prediction direction of $\hat{\boldsymbol{\eta}}$.

Algorithm1: PLS-DVHop Localization Algorithm

Input $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_m]$: hop-counts matrix of beacons; $\mathbf{D} = [\mathbf{d}_1, \mathbf{d}_2, \cdots, \mathbf{d}_m]$: Euclidean distances matrix of beacons; k : the number of principal element; $\{\mathbf{c}_i = (x_i, y_i)\}_{i=1}^{m}$: the location of beacons

output $\{\hat{\mathbf{c}}_i = (x_i, y_i)\}_{i=m+1}^{n}$: estimated location of the non-beacons

1 Centring matrix **H** and matrix **D**

2

for $j = 1, \cdots, k$

$\mathbf{u}_j$ = first column of $\mathbf{H}_j^T\mathbf{D}$

$\mathbf{u}_j = \mathbf{u}_j / \|\mathbf{u}_j\|$

repeat

$\mathbf{u}_j = \mathbf{H}_j^T\mathbf{D}\mathbf{D}^T\mathbf{H}_j\mathbf{u}_j$

$\mathbf{u}_j = \mathbf{u}_j / \|\mathbf{u}_j\|$

until convergence

$$\mathbf{w}_j = \frac{\mathbf{H}_j^T\mathbf{H}_j\mathbf{u}_j}{\mathbf{u}_j^T\mathbf{H}_j^T\mathbf{H}_j\mathbf{u}_j}$$

$$\mathbf{c}_j = \frac{\mathbf{D}_j^T\mathbf{H}_j\mathbf{u}_j}{\mathbf{u}_j^T\mathbf{H}_j^T\mathbf{H}_j\mathbf{u}_j}$$

$\hat{\mathbf{D}} = \hat{\mathbf{D}} + \mathbf{H}_j\mathbf{u}_j\mathbf{c}_j^T$

$\mathbf{H}_{j+1} = \mathbf{H}_j(\mathbf{I} - \mathbf{u}_j\mathbf{w}_j^T)$

end

$\hat{\boldsymbol{\eta}} = \mathbf{U}(\mathbf{W}^T\mathbf{U})^{-1}\mathbf{C}^T$

3 Putting the obtained estimation term $\hat{\boldsymbol{\eta}}$ into the original equation to figure out the prediction model; putting the hop-counts from unknown nodes to known nodes into the equation to further figure out corresponding estimation distance. At the moment, integrating coordinates and estimation distance of known nodes, least squares may be used to estimate unknown nodes, so as to obtain the estimation coordinates.

PLS is a multivariate data analysis method integrates multivariate regression, canonical correlation analysis and principle component analysis altogether. It makes use of covariance of input and output to guide feature selection, which perfect fits for modelling and prediction of real situation. Being applied in DV-Hop localization method, PLS is fit for different localization situation, and is able to obtain high localization accuracy. At the moment, hop-count and Euclidean distances modelling process based on PLS may be concluded as Algorithm 1.

5 Performance evaluations

One of the important features of range-free localization method is that, it is quite fit for large-scale deployment. This requires thousands of sensor nodes, while in labs; it is difficult to realize such large-scale real network. As for this, in researches on large-scale range-free node localization algorithm, software simulation is often applied to estimate the advantages and disadvantages of localization algorithm.

In this section, the performance of PLS-DVHop algorithm is to be analysed and assessed via simulation experiment. Matlab2013b software is employed to analyse and compare methods proposed in this paper. In the experiment, all nodes are evenly distributed in two-dimensional space. In order to reduce the one-sidedness of single experiment, each deployment goes through 50 simulations while nodes in each experiment are randomly re-distributed in the experiment area. Mean value of 50 RMS (Root Mean Squares) [18] is taken as the assessment basis.

In order to assess the performance of methods proposed in this paper, nodes are assumed to be randomly or regularly deployed in the monitoring area. In addition, in order to evaluate the adaptability of the proposed methods to network topology anisotropy, obstruction is added in the aforementioned two deployment strategies, i.e. assuming that there is a large obstruction in the deployment area, impeding the direct communication between nodes. Such area is of C-Shape. In allusion to different network topology structure, nodes are re-deployed in the same area for several times, assessing the average localization error. This experiment also compare our method with three previous methods:

1) The classic DV-Hop method proposed in [7];

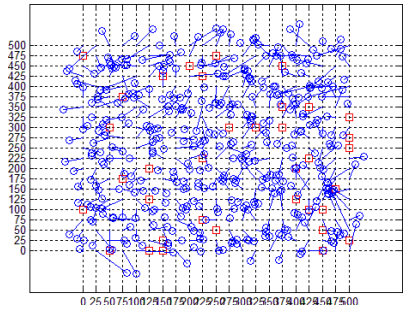
2) PDM proposed in [11];

3) LSVR proposed in [13] in two group experiments.

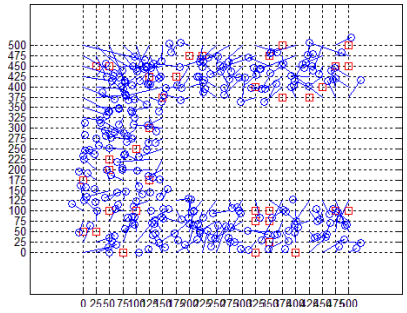
Furthermore, for fairness, in PDM localization, we denoted abandoning threshold in TSVD as 2, i.e. abandoning eigenvectors with eigenvalue less than or equal to 2. There is certain relationship between kernel parameter σ and the distance between training samples. In the experiment, we assume σ as 50 times of the average distance between sample nodes. Configuration of C and ε in SVR method uses for reference related reference [19], while C is also configured based on σ according to related reference [20]

5.1 REGULARLY DEPLOYED SENSORS

In this group of experiments, there are 441 and 315 nodes deployed in the area of square or C-Shape region. The number of beacons was gradually increased from 30 to 50, with a step size of 2.before analysing the performance of PLS-DVHop algorithm, let us first investigate the two final localization results (in figure the number of beacons is 36). In Figure 2, the circles denote the unknown node and the squares are the beacon node, the line connects the actual coordinate and estimated coordinate of unknown nodes, and the longer the line, the more the estimated value deviates from the actual location.



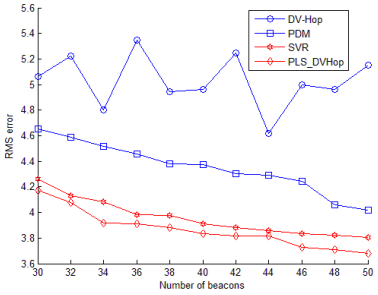
a) Square Regular Distribution



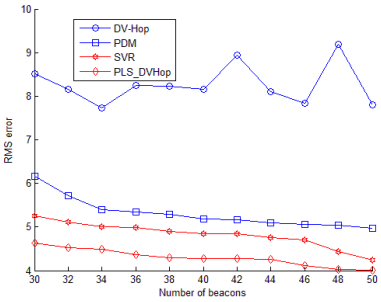
b) C-shaped Regular Distribution

FIGURE 2 Localization Results Under Regular Distribution

Figures 3a and 3b describes the influence of beacons quantity on localization accuracy in regular deployment network. Theoretically, more beacons in monitoring area leads to smaller localization error. According to the result shown in Figures 3a and 3b, RMS error of DV-Hop is the largest, and the curve fluctuates up and down. RMS error of the other three methods simply decreases with the number of beacons grows. PLS-DVHop algorithm proposed in this paper takes on highest localization accuracy. In addition, RMS error of PLS-DVHop and LSVR method are similar in the two deployment area. By contrast, the rest methods take on significant difference. This also shows that PLS-DVHop and LSVR methods have high environment adaptability, and are fit for anisotropic networks. As PLS-DVHop is multivariate regression method, in calculation process, it considers correlation between nodes. Thus, its localization accuracy is the highest. It may as well be seen from Figure 3 that, PLS-DVHop monotonically decreases with the number of beacon increases. Yet, such tendency is weak. This also indicates that, the number of beacons has quite slight influence on precision of the algorithm. PLS-DVHop method is also fit for environment with fewer beacons.



a) RMS error under Square Regular Distribution

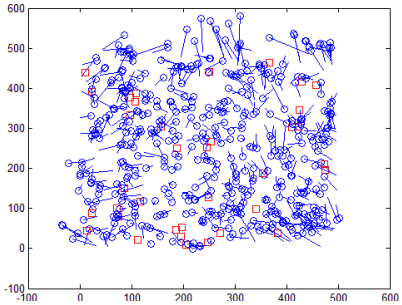


(b) RMS error under C-Shape Regular Distribution

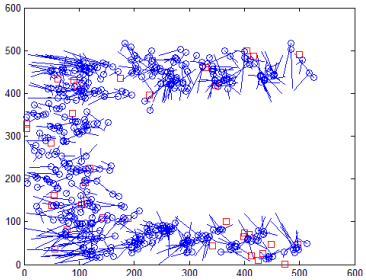
FIGURE 3 RMS error Under Regular Distribution

5.2 RANDOM DEPLOYED SENSORS

In this group of experiments, 500 nodes were randomly deployed in a 500×500 two-dimensional square area, and 30 to 50 nodes were chosen from the 500 as the beacon nodes. Like the regular deployment, in order to investigate the impact of non-line-of-sight on the localization algorithm, the experiment scenario with obstacle was added to the random deployment experiment. Similarly, the two final localization results were analysed first. As shown in Figure 4, in these two experiments, the number of beacon nodes is still 36.



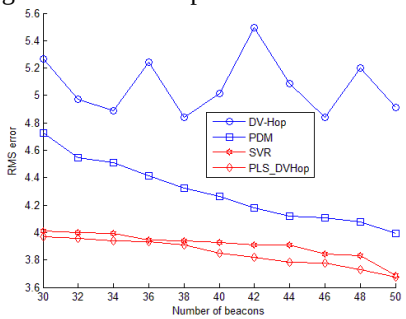
a) Square Random Distribution



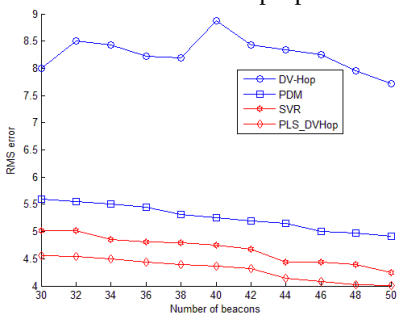
b) C-Shape Random Distribution

FIGURE 4 Localization Results Under Random Distribution

Figures 5a and 5b describes the relation between beacon quantity and RMS error in random deployment network. Similar to regular deployment, RMS error of DV-Hop is the highest, and the curve fluctuates up and down. Moreover, in C-shaped region, the localization error is larger than that in square region. This proves that, DV-Hop method is instable, and is sensitive to anisotropy of network topology. PDM method eliminates some data of small eigenvalue. As the elimination is set manually, disregarding factors of hop count and real distance dimension, its localization accuracy is only slightly improved than DV-Hop method. The localization accuracy of LSVR method is quite close to the method proposed in this paper. Yet, LSVR is a multi-input and single-output method, and is powerless when establishing inter-matrix relation like hop-counts and real distances. LSVR method has to perform frequent modelling. Although being optimized, it still does not considered correlation between data. Thus, the localization accuracy of SVR-based method is lower than the method proposed in this paper.



a) RMS error under Square random Distribution



b) RMS error under C-Shape random Distribution

FIGURE 5 RMS error Under random Distribution

6 Conclusions

In this paper, a range-free localization method (PLS-DVHop) is proposed. The method establishes the relation between hop-counts and Euclidean distances, so as to build measurement distance (hop-counts) and Euclidean distance model, and to effectively solve complicated topological structure problem in WSN. Compared with other similar methods, PLS-DVHop method inherits the advantages of DV-Hop method. Shown by simulation test, under different deployment environment, PLS-DVHop algorithm is able to present high positioning accuracy, and is only slightly affected by the number of beacon.

Abstract

The basic concept of dynamic characteristics of spindle is introduced. The first ten order vibration mode and natural frequency of shaft are obtained by modal analysis and harmonic response analysis using software ANSYS. The deformation trend of spindle under resonance state is analysed and the contrast between theory and simulation critical speed is done. The frequency response curve of spindle is given. The first order, second order dynamic stiffness and dynamic stiffness under general conditions are calculated. The influence of bearing damping to spindle dynamics characteristics is discussed. In the end, the measures of improving spindle performance are summarized.

Keywords: Shaft, Dynamic characteristic, ANSYS, modal analysis, harmonic response analysis

1 Introduction

In actual manufacturing, cutting force and other exciting forces are applied in the form of dynamic load onto the structure. In order to ensure the manufacturing accuracy and efficiency of work piece, not only the spindle system of machine tool should have some static rigidity, but also the dynamic property of spindle structure should be considered. The dynamic property of spindle structure refers to its resistance to forced and self-excited vibration. Notably in high-speed precise machine tool, the dynamic property of spindle usually has great influence on the quality of manufactured goods [1]. For a long time, researches on the dynamic property of spindle have mainly adopted analogies of experience or other methods, which brings about some negative effects, such as prolonged product development cycle, relatively higher cost and blindness. In addition, its theoretic calculation method is found to be extremely difficult for relatively complex structures. Virtual electrodynamics research is therefore proposed. It mainly constructs the model of finite element analysis of digital mock-up through some large-size finite element analysis software to make dynamics analysis accordingly, which can be used to know the dynamics property of digital mock-up. In this way, product design cycle and cost incurred would be reduced with specific target. This paper focuses on the spindle of HTC3250μn and HTC2550hs CNC turning centre, and uses ANSYS software to research the dynamic properties of this machine tool spindle. This greatly simplifies the performance analysis process of spindle unit, lessens the intervention of manual operation and avoids repetitive work.

At present, the researches on dynamic property can be mainly classified into two respects: natural vibration characteristics and response characteristics. Wherein, the research of natural vibration characteristics focuses on undamped free vibration, which can be used to get the natural property of vibration system, namely natural frequency and vibration mode; while the research of response characteristics focuses on the steady-state response of structure that is sinusoidal-varying with time, which can be used to calculate the dynamic response of structure and get the displacement response and stress response [2].

2 Spindle modal analysis

2.1 SUMMARY OF MODAL ANALYSIS

Modal analysis is a kind of technology used for determining the natural frequency and vibration mode of the structure (Natural frequency and vibration mode of the structure are two extremely important parameters in designing the structure on dynamic loads) [3]. The natural frequency reflects the degree of structure rigidity, namely bigger natural frequency means bigger rigidity. Through modal analysis, the structure can be designed to avoid resonance or vibration at specific frequency, designers would know how the structure responds to the dynamic loads of different types, and control parameter will be provided for other dynamic analysis as well. As the structure vibration characteristics determines its response status at different dynamic loads, modal analysis is the basis for further analysing structure dynamics, such as transient dynamics, harmonic response and spectral analysis.

Machine tool vibration forces the change on relative position between cutting tool and work piece as well as relative speed, which changes the cutting process and limits the product manufacturing precision and efficiency. Most vibrations of machines tool come from the spindle.

[*] ***Corresponding author*** e-mail: 52425362@qq.com

Therefore, the natural frequency and vibration mode of spindle are important metrics for analysing and evaluating the dynamic performance of machine tool. Although the spindle of machine tool is an infinite multi-degree of freedom system with infinite multiple natural frequencies and their corresponding vibration modes, the low-order mode of the spindle is actually enough to express its dynamic property. Therefore, a few of low-order modes starting from the first-order mode are enough to make a finite element modal analysis of the machine tool.

The steps of making a modal analysis by ANSYS software are more or less the same with other analyses, but it should be emphasized that the application of constraint and boundary condition on the modal analysis will affect the result to a larger degree. In this concern, a proper application of boundary condition is necessary to accurately get the natural frequency of structure. Normally the mode extraction methods are described as below:

1) Block Lanczos Method: it is applicable to the solution of the eigenvalue of large-size symmetric matrix, which has the characteristics of lower quality requirement of model unit and faster solution availability;

2) Power Dynamics Method: it is applicable to multi-degree of freedom problems, especially for only solving the first several orders of structure;

3) Unsymmetric Method: it is used for the problems when the system matrix is unsymmetric;

4) Damped Method: it is used for problems considering damp effect; this paper uses this method as the bearing damp effect cannot be ignored.

In typical modal analysis, the only effective load is zero-displacement constraint. If one non-zero displacement constraint is appointed at some point of DOF, the program will replace the position of this DOF with zero-displacement constraint. Although other types of loads can be appointed in modal analysis, such as force, stress, temperature and acceleration, they are invariably ignored in modal extraction. All loads vector will be calculated by the program and saved in vibration mode documents, which can be used in harmonic response analysis or transient analysis by the mode superposition method.

2.2 SPINDLE MODAL ANALYSIS BASED ON ANSYS

In order to get an accurate result of the spindle modal analysis, this paper properly modifies the constructed three-dimensional static analysis model, which would be used as the finite element model for spindle modal analysis. The researcher alters the analysis type to modal analysis in the solver, and sets the frequency range of extracted mode from the minimum "0" to the maximum "3000". Spring damped unit is used to simulate the boundary condition and supporting form, the pitch point of inner ring is noted to restrict the axial degree of freedom , partial useless natural frequency and vibration mode are filtered out, and the spindle modal analysis and modal extension are finally made. Calculated by ANSYS software, the first 10-order modes of spindle are extracted to get their vibration characteristics. Vibration modes diagram are shown as Fig.1. From Fig.1, the vibration modes of spindle are mainly torsion, oscillation and bend. First-order displays the vibration mode of rigid body; the natural frequencies for two-order and three-order, four-order and five-order, six-order and seven-order are the same and vibration modes are in orthogonal, which can be mathematically understood as different characteristic vectors for one same characteristic value or multiple root, but the deformation trends are differently from one another.

FIGURE 1 Vibration mode of spindle: a) First-order Vibration Mode, b) Second-order Vibration Mode, c) Third-order Vibration Mode, d)Four-order Vibration Mode, e) Five-order Vibration Mode, f) Six-order Vibration Mode, g) Seven-order Vibration Mode, h) Eight-order Vibration Mode, i) Nine-order Vibration Mode, j) Ten-order Vibration Mode

Through a separate analysis of all acquired vibration diagrams, combined with the natural frequencies for all orders calculated by ANSYS software, the vibration characteristics of spindle can be summarized as shown in Table 1.

TABLE 1 Natural vibration frequency and mode of spindle

Degree	Frequency(Hz)	Vibration Mode
1	0	Translational
2	865.36	First-order Z oscillation
3	865.36	First-order Y oscillation
4	1060.4	Two-order Y oscillation
5	1060.4	Two-order Z oscillation
6	1585.8	Three-order Y oscillation
7	1585.8	Three-order Z oscillation
8	1936.1	Torsion

In actual, the modal analysis of spindle can be made by use of the two-dimensional finite element analysis model as well. Although the natural frequency solved by the two-dimensional finite element analysis model is basically the same with that of three-dimensional finite element analysis model, the solved vibration mode isn't as resourceful as that of three-dimensional finite element analysis model, which is mainly caused by huge difference of nodes quantity among different unit types as well as the consideration of different treatment methods for boundary conditions. Therefore, the calculation simulation effect of three-dimensional finite element model proves to be more accurate.

2.3 ANALYSIS OF SPINDLE CRITICAL SPEED

Traditionally, critical speed of spindle mainly refers to the spindle natural frequencies at all orders. As the common spindle has the characteristic of relatively lower working speed, the influence of spindle speed on the dynamic characteristics can be ignored. Therefore, the traditionally defined critical speed is reasonable.

With the growing speed of machine tool, the traditional definition of critical speed cannot meet the requirement of high-speed spindle. In this concern, the influence of speed cannot be ignored in the dynamic analysis of high-speed spindle. The critical speed of high-speed spindle is defined as the corresponding speed at one natural frequency. In the analysis of high-speed spindle critical speed, the spindle will resonate when the rotation frequency of spindle equals its natural frequency. However, if this case should occur in actual manufacturing, it not only impairs the manufacturing quality, but also irreversibly damages the spindle, reduces its service lifetime and increases the maintenance cost.

At a specific speed, the deflection of spindle can be arbitrary value, wherein the deflection at each point can be arrayed in an elastic straight line. The specific speed is namely the critical speed as output in Equation (1).

$$w_c = l^2\sqrt{\frac{EJ}{m}} = \frac{(la)^2}{a^2}\sqrt{\frac{EJg}{A\gamma}}, \quad (1)$$

Wherein, $la = \pi, 2\pi, 3\pi$, A is the cross-sectional area of spindle segment, and γ is the material density.

Actual and ideal structure of spindle differs in the uniform section of shaft end, and the critical speed of actual structure has slightly higher critical speed as output from Equation (1). In most cases, the critical speed of spindle can be directly output through Equation (2) with the unit of speed converted to r/min.

$$n = 60f, \quad (2)$$

Wherein, n is the speed, f is the natural frequency. The critical speeds of spindle at all orders can be calculated by the natural frequency through ANSYS, but it starts from the two-order frequency because the first-order is the vibration mode of rigid body. Among all critical speeds of spindle at all orders as listed in Table 2, the low-order speed of spindle is of most referential value. However, the low-order speed value output from theoretical equation is in discrepancy with the actual value unless the design speed is within the absolute safety range; or otherwise it may easily result in irrecoverable result caused by misjudgement. In order to accurately get the critical speed of spindle, it can be calculated much closer to the actual value through ANSYS, which would avoid the misjudgement.

TABLE 2 Critical speed of spindle (Theoretical value)

Degree	Frequency(Hz)	Speed(r/min)
2	865.36	51921.6
3	865.36	51921.6
4	1060.4	63624
5	1060.4	63624
6	1585.8	95148
7	1585.8	95148
8	1936.1	116116

The speed of spindle is set as 0rad/s, 5000rad/s, 10,000rad/s and 15,000rad/s respectively for modal analysis, and Campbell Diagram [4] is eventually drawn up as shown in Fig.2.

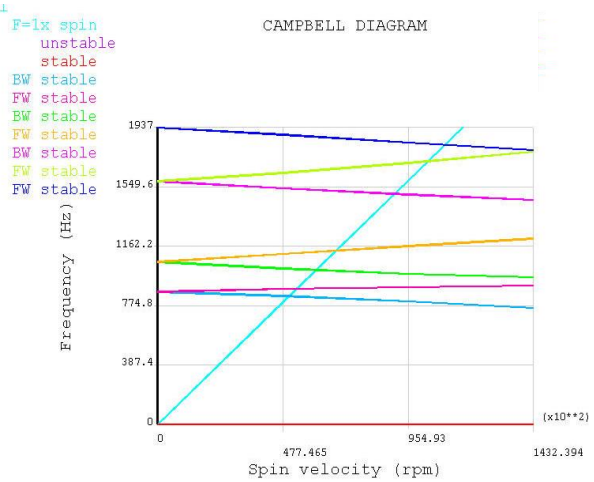

FIGURE 2 Campbell diagram for critical speed

Though Campbell Diagram we can find there are two curves diverging from each natural frequency, wherein one curve increases with the speed, while the other one decreases with the speed. These are called as forward precession frequency and backward precession frequency respectively in rotor dynamics. According to the definition of critical speed, the speed at the cross point between the 45°straight line as shown in Campbell diagram and forward precession frequency curve is the critical speed [5] at this very moment. The critical speed of spindle (Simulation value) is shown in Table 3. In comparison between the values in Table 2 and Table 3, the critical speed of spindle calculated by drawn-up Campbell diagram through ANSYS is approximately 1% higher than the critical speed by theoretical equation. The equation for critical speed of forward precession is described as Equation (3):

TABLE 3 The critical speed of spindle (Simulation value)

Degree	Frequency(Hz)	Speed(r/min)
2	865.36	52372.3
3	865.36	52372.3
4	1060.4	64707.8
5	1060.4	64707.8
6	1585.8	97252
7	1585.8	97252
8	1936.1	118458

$$\left|(-[M_1]+[J_1])\omega^2+[K_{g1}]=0\right|. \tag{3}$$

Through it we can find the critical speed would invariably increase if there is any forward precession, which is found to be in conformity with the reality; the highest design speed of HTC3250μn and HTC2550hs CNC turning centre is 6000r/min, which is lower than 2/3 of the first-order critical speed. Consequently, the spindle would not have natural vibration in actual use, which meets the running requirement.

3 Harmonic response analysis of spindle

3.1 SUMMARY OF HARMONIC RESPONSE ANALYSIS

Harmonic response analysis is a technology used to solve the structure response under the simple harmonic load when the frequency is known. The input value is the harmonic load (force and forced displacement) that its size and frequency is known, or under multiple loads at the same frequency, the output value is the harmonic displacement [3] at each degree of freedom. In actual manufacturing, cyclic exciting force will apply on the spindle when the machine tool runs. When the natural frequency of spindle equals the frequency of cyclic exciting force, resonance effect will take place. During actual manufacturing, resonance will not only reduce the manufacturing accuracy that result in rejected parts, but also impair the machine tool and cutting tool. As a result, it is necessary to make a harmonic analysis of spindle in the phase of designing the spindle.

In ANSYS, the finite model of harmonic response analysis is more or less the same with the finite model of modal analysis. Full method requires a direct integral computation, which would invariable consume a great amount of time; comparatively, the method of mode superposition directly multiplies and sums the obtained modal type through modal analysis, which has the characteristics of quickness, high efficiency and well-intended accuracy. To that regard, this paper adopts the method of mode superposition to make a harmonic response analysis.

3.2 HARMONIC RESPONSE ANALYSIS OF SPINDLE BASED ON ANSYS

Before making a harmonic response analysis of the spindle, the load changing in line with time shall be determined, or the exciting force shall be determined. The equation for typical exciting force can be expressed as follows:

$$F(t)=F_1\sin(\omega t+\phi), \tag{4}$$

wherein, F_1 stands for the amplitude of exciting force; ω stands for the range of forced vibration frequency; and ϕ stands for the phase angle. The amplitude of exciting force is actually the maximum value of external load; the range of forced vibration frequency refers to the frequency range of simple harmonic load; and the phase angle refers to the metric for load lagging or preceding the reference time [6]. In this paper, the amplitude of exciting force is turning force, which is to be put into the equation. Equation (4) in the manner of Fourier series is extended:

$$\begin{aligned}F(t)=F_0+F_1\sin(\omega t+\phi_1)\\ +F_2\sin(\omega t+\phi_2)+\cdots\end{aligned}. \tag{5}$$

If the higher order term is not considered, ϕ_1 is approximated to be "0", therefore the exciting force equation is further simplified as below:

$$F(t)=F_1\sin(\omega t). \tag{6}$$

According to general manufacturing, the vibration range is between 0 to 600Hz. In this way, the exciting force of harmonic response analysis is finally determined.

In the above part, the modal analysis is made on the spindle, which is followed by the harmonic response analysis after saving and analysing the result. In view of large time consumption in an accurate harmonic response analysis, this paper firstly analyses the entire range of vibration frequency, and gets the spindle radial response displacement curve within the range of vibration frequency by reducing the sub-steps and analysing time. Due to limited sub-steps, this curve only shows the

approximate position of change tendency and vibration points. In order to obtain the spindle radial response displacement in a more accurate way, accurate analysis could be made within one frequency range respectively. By adding more sub-steps within this frequency range, more accurate analysis result can be obtained to evaluate the response characteristics of spindle.

In time-history postprocessor of ANSYS, the response relationship between variable and frequency cannot be observed until the observable variables are defined. In reality, the definition of variable directly determines the result of spindle response analysis. Generally, dangerous points in the spindle shall be contained in those observable variables. In case some dangerous points are ignored, the evaluation of spindle response characteristics would possibly be erroneous, the dynamic rigidity of spindle would deviate, which would lead to the manufactured machine tool lower than the required precision of actual manufacturing.

In this concern, this paper intends to analyse the five dangerous points of spindle, combined with the analysis of spindle front-end, front prop, rear prop, middle point and rear-end, so that the spindle response characteristics can be obtained. In order to compare the influence of the damping of bearing on the dynamic characteristics of spindle, respective discussions under damping and absence of damping must be made. Set 0-1200Hz as the excitation frequency, through harmonic response analysis, the radial amplitude-frequency curves for spindle front-end, front prop, rear prop, middle point and rear-end can be shown in Figure 3.

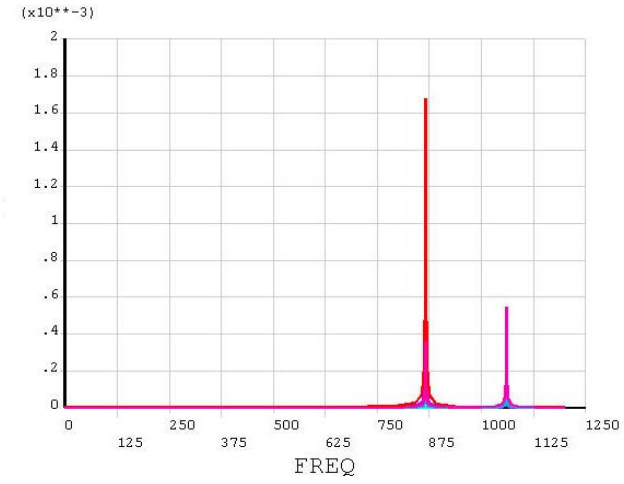

FIGURE 3 Displacement-frequency curve of spindle(0～1200Hz)

Figure 3 shows there are significant resonances at two natural frequencies: 865Hz and 1060Hz, which also shows bigger fluctuation of deformation amplitude. As a result of no damping, the vibration amplitude has the infinite tendency to increase and dynamic rigidity significantly declines, when the spindle does not meet the manufacturing requirement. In order to better reduce the influence of spindle vibration on the manufacturing precision, damping is usually introduced to reduce the vibration response amplitude of spindle. The bearing damping in this paper is set as 5000 $N \cdot S / \mu m$, and the excitation frequency is set as 0～1200Hz. Through the harmonic response analysis, the amplitude-frequency curves for spindle front-end, front prop, rear prop, and middle-point, rear-end can be shown as Figure 4. The Figure 4 shows there are significant resonances at two natural frequencies: 865Hz and 1060Hz, while in consideration of damping effect, the vibration amplitude would significantly decline. The discussion is respectively made for two resonance points in the following part.

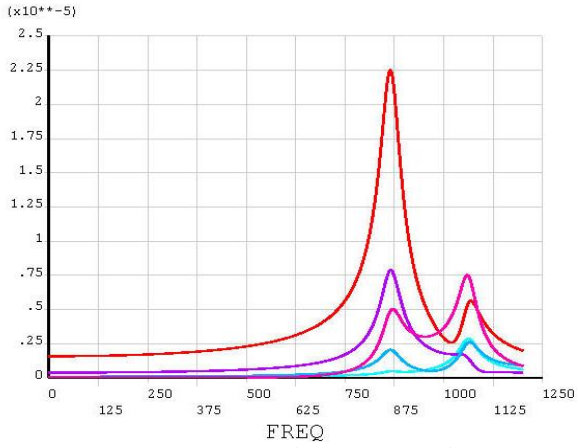

FIGURE 4 Displacement-frequency curve of spindle (0～1200Hz)

Set 400～900Hz as the range of excitation frequency, control the sub-steps as 5,000, and reanalyse the harmonic response, which is shown in Figure 5 and Figure 6.

Figure 5 and Figure 6 show that the dynamic stiffness of spindle remains almost unchanged before the excitation frequency could approximately reach the first-order natural frequency. When it closes to the natural frequency, the response displacement begins to upward while the spindle stiffness begins to downward. When it reaches the resonance point, the response displacement is the highest and the spindle dynamic stiffness is the lowest. After that, the response displacement begins to downward, while the spindle dynamic stiffness gradually upwards.

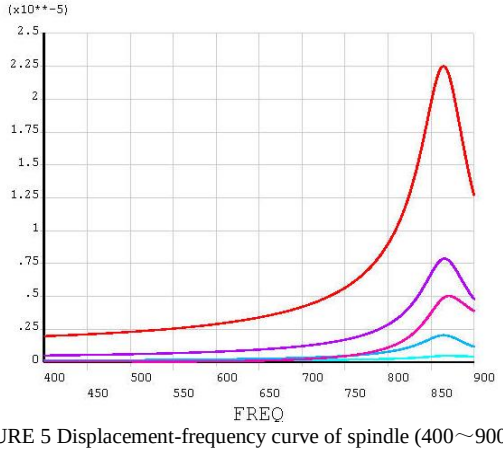

FIGURE 5 Displacement-frequency curve of spindle (400～900Hz)

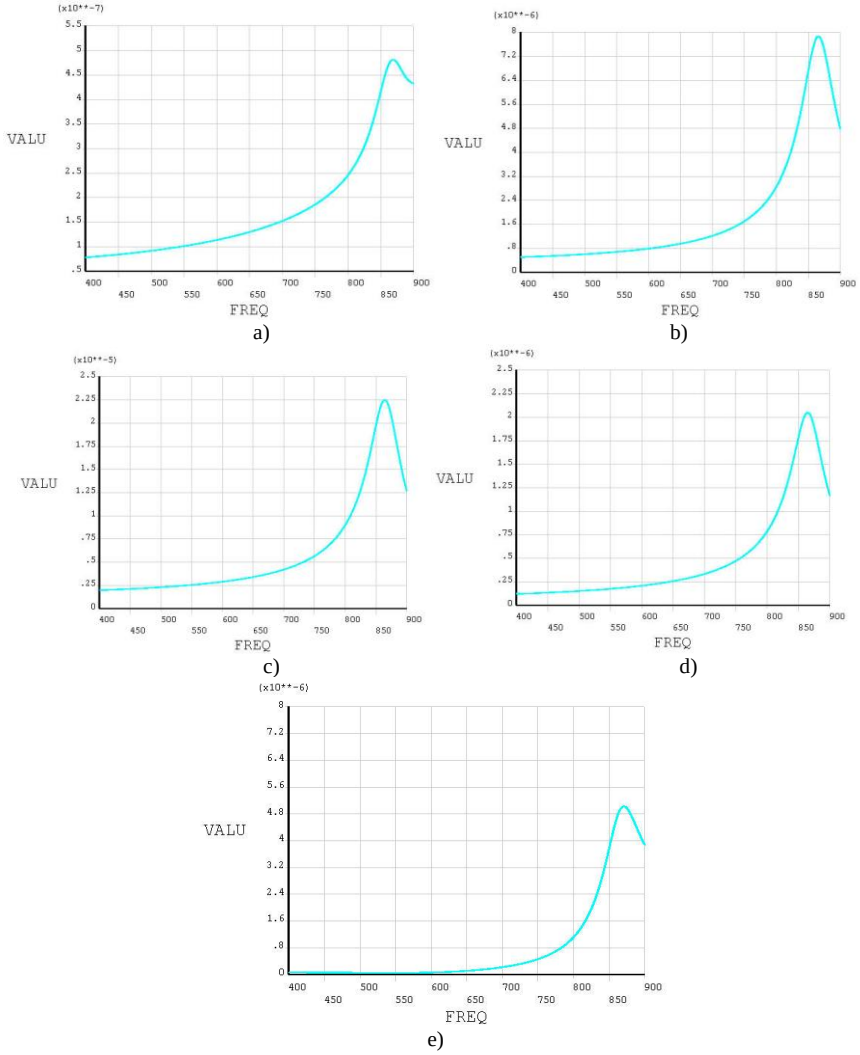

FIGURE 6 Displacement-frequency curve of spindle (400～900Hz): a) Displacement-frequency curve of front bearing, b) Displacement-frequency curve of rear bearing, c) Displacement-frequency curve of spindle front-end, d) Displacement-frequency curve of spindle rear-end, e) Displacement-frequency curve of spindle middle-point

Through the analysis of all spindle points, roughly around the first-order natural frequency, the displacement response of spindle front-end is more significant, and at 865Hz, the response displacement abruptly increases to 22.5 μm . The spindle dynamic stiffness significant downwards; after that the displacement response abruptly decreases while the spindle dynamic stiffness gradually upwards. During this process, the minimum dynamic stiffness of spindle is shown as below:

$$K = \frac{452.9}{22.5} = 20.13N / \mu m . \quad (7)$$

In view of the analysis around spindle two-order resonance points, set 900～1400 Hz as the range of excitation frequency, control sub-steps as 5,000, select five key points on the spindle to draw up the amplitude-frequency characteristic curve and make harmonic response analysis, the result is shown as Figure 7. Figure 7 shows the displacement response under the influence of spindle exciting force is lower than the first-order resonance point, when the spindle is at the two-order resonance point. However, the spindle vibration at this order remains evident, and the spindle stiffness shows the tendency of upward, downward and gradually upward after leaving the resonance point. The displacement-frequency curves for all key observing points are shown in Figure 8.

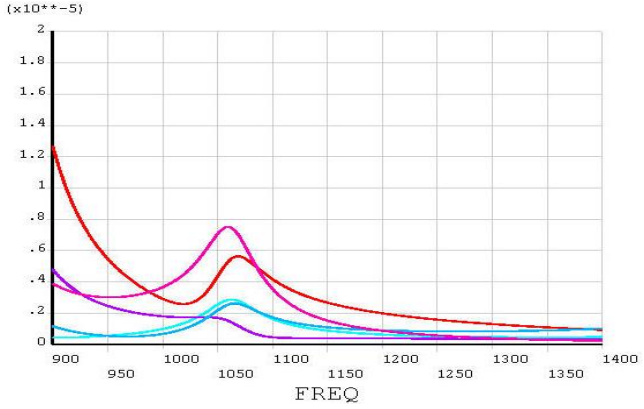

FIGURE 7 Displacement-frequency curve of spindle (900～1400Hz)

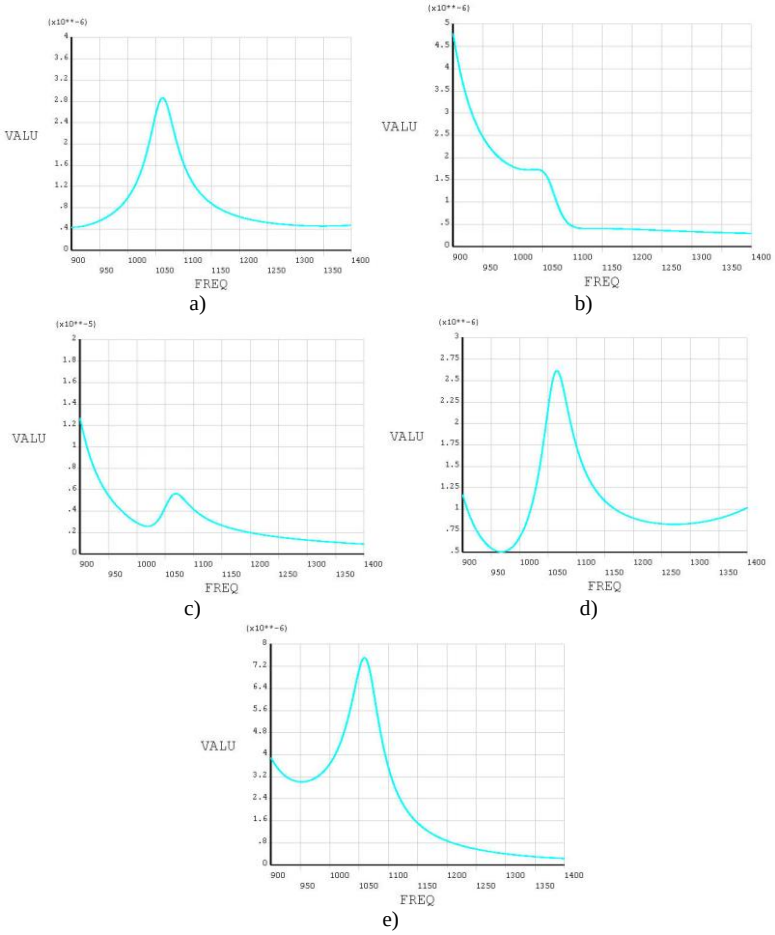

FIGURE 8 Displacement-frequency curve of spindle(900～1400Hz): a) Displacement-frequency curve of front bearing, b) Displacement-frequency curve of rear bearing, c) Displacement-frequency curve of spindle front-end, d) Displacement-frequency curve of spindle rear-end, e) Displacement-frequency curve of spindle middle-point

Through the analysis of each point on the spindle, it can be found that the displacement response of middle point is the most prominent around the second-order natural frequency. At 1060Hz, response displacement increases suddenly and the maximal displacement increases to 7.8 μm . The dynamic stiffness of spindle declines, thus it can be judged that spindle is prone to crack at the moment. Then displacement response suddenly declines and spindle dynamic stiffness gradually improves. During this process, the smallest dynamic stiffness of the spindle is as follows:

$$K = \frac{452.9}{7.8} = 58.06N / \mu m . \tag{8}$$

By comparing the amplitude of the first-order resonance point and two-order resonance point, the spindle vibration tendency matches with the modal vibration as solved in the previous part. The spindle vibration tendency does not increase strictly with the increase of natural frequency, but its amplitude usually depends on the mutual effect of characteristics and damping.

The above analysis can be used to evaluate the vibration characteristics at the time of spindle resonance. However, when applied to the actual manufacturing, as the spindle keeps off the forced resonance area at the designing phase, the analysis of the resonance point cannot completely evaluate the spindle dynamic characteristics. In order to cover this point, according to the variation range of excitation frequency at the normal state of manufacturing, the analysis result of spindle harmonic response can be shown in Figure 9. Figure 9 shows the response displacement of all spindle points increase with the excitation frequency, notably on the spindle ends and front-end bearing. At 600Hz, the maximum response amplitude is 2.9 μm , when the spindle dynamic stiffness can be expressed as:

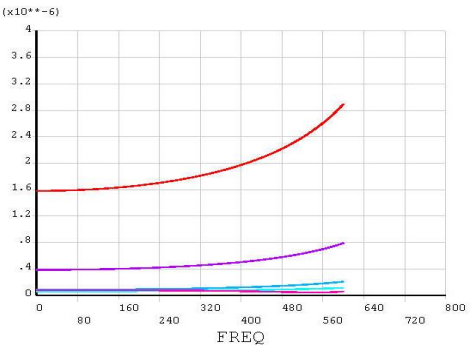

FIGURE 9 Displacement-frequency curve of spindle(0～600Hz)

$$K = \frac{452.9}{2.9} = 156.17N / \mu m . \quad (9)$$

By analysing the dynamic stiffness, it can be concluded that the spindle adopted in this paper meets the design requirement; in actual manufacturing, it can meet the precision requirement.

4 Conclusions

The performance analysis and optimization of the spindle based on ANSYS can effectively shorten the design time and improve design efficiency. Through the dynamic characteristics analysis of spindle, it can be summarized that the following method can improve the dynamic characteristics of spindle:

(1) Improving the stiffness and damping of bearings. From the vibration diagram and harmony response analysis of spindle, it can be clearly found that the deformation around the front support of spindle is more obvious. Thus, improving the stiffness and damping of the front bearing can effectively reduce the vibration deformation in the area, improve the natural frequencies of spindle and avoid the happening of resonance phenomena.

(2) Improving the structure of spindle. The configuration way of bearing, spindle span and length of overhanging end has very important influence to the dynamic characteristics of spindle. On the premise of conditions permit, the structure optimization design can significantly improve the dynamic characteristics of spindle.

Abstract

In order to pull the fractional-order theory to better application, the detailed of computer numerical simulation of the Adams-Bashforth-Moulton Algorithm is proposed in this paper. Anti-synchronization of a class of fractional-order chaotic system with uncertain parameters is realized on this basis and the stability theorem of the system is presented at the same time. And thus it indicates that this method can be adapted to chaotic system with certain parameters and a class of chaotic system with not equal fractional-order. And corresponding implementation conditions is given as well. Besides, it is pointed out that the method, which unites the synchronization and anti-synchronization is also suitable for synchronization issues of the system. Finally, take classic Lorenz system for instance, track time domain and error map about drive system and response system of anti-synchronization are given. The results prove the effectiveness of the control method in the realization of anti-synchronization of a class of fractional-order chaotic system with uncertain parameters and the feasibility of fractional order computer numerical simulation

Keywords: fractional-order, chaotic system, anti-synchronization, chaos control

1 Introduction

Fractional calculus is known as a more common form of integer order, and it also has its own unique features - memory function, meanwhile, a growing number of scientific workers have been attracted to fight for it gradually [1-6]. As for fractional definitions and mathematical description, it has gained initial achievements, but how to make a more accurate numerical simulation analysis through computer is still in its infancy. It is can be predicted that computer numerical simulation of fractional order system will greatly promote the engineering applications of fractional order [7-9], meanwhile, it will certainly open up another important research area of computer applications, which will help us describe the objective world better.

Chaos is a movement pattern of nonlinear system, whose feature is a special, unstable and class of random. The system in a chaotic movement is usually called chaotic system, which was first found by the U.S. meteorologist Lorzenz in his proposed meteorological equations. With further research, the discovery and understanding of chaotic feature began to shift to the control and use of it. In 1990, physicist Ott. Grebogi and Yorke at the university of Maryland successfully controlled chaos by parameter perturbation method (i.e. OGY method), which is an iconic achievement. Closely followed, Pecora and Carroll first raised a synchronization scheme of two similar chaotic systems with different initial conditions, which is called PC method. Since then, Control of Chaotic Synchronization has aroused widespread concern. So far, various control methods of Chaotic Synchronization have been proposed by domestic and foreign scholars, such as adaptive control method [10, 11], Backstopping control method [12], fuzzy control [13, 14], sliding mode control [15, 16], etc. With the deepening of the research, the concept of synchronization has also been expanded, which includes anti-synchronization, generalized synchronization, projective synchronization, phase synchronization, trailing synchronization, etc. [17-19]. Among them, the anti-synchronization is a very interesting concept, which means a state that the drive system and response system achieve equal magnitude but opposite in sign.

In real industrial practice, the noise is ubiquitous, and many system parameters of the system cannot be accurately measured, and even unknown. In order to better realize the engineering practical value of computer numerical simulation, it is very meaningful to consider the uncertainty of noise and parameter, and it has preliminary obtained some related research results [20-22].

In summary, anti-synchronization of a class of fractional-order chaotic system with uncertain parameters is studied in this paper, and a stability theorem of the system is presented. Besides, this method is also suitable to chaotic system with certain parameters、drive and response systems with unequal Fractional Order and synchronization of a class of fractional-order chaotic

system. Finally, take classic Lorenz system as an example, the detailed iterative formula of computer numerical simulation of the Adams-Bashforth-Moulton Algorithm is proposed, and the results of computer numerical simulation are given.

2 Description of fractional system

Theorem 1 [23] a general fractional order linear system can be described as

$$D^q x = Ax, \tag{1}$$

where $q=[q_1,q_2,\ldots,q_i,\ldots,q_n]$ and $(0<q_i\le 1)$. If and only if all eigenvalues λ_i of matrix A is satisfied with $|\arg(\lambda_i)|>q\pi/2$, the system (1) is absolutely stable.

In this paper, a class of fractional order chaotic systems with uncertain parameters is presented as:

$$D^\alpha x=(A+\Delta A)x+f(x). \tag{2}$$

Its response system is

$$D^\beta y=(A+\Delta A)y+f(y)+U(x,y), \tag{3}$$

where $x,y\in R^n$ are all n-dimensional state vectors; f is a continuous vector function; $U(x,y)$ is the designed cont roller; α and β are the fractional orders; A is the coeffic ient matrix of the fractional order system; ΔA indicates u ncertain parameters, which satisfies $\|\Delta A\|\le\delta<M$. By th e way, M is a constant.

Our goal is to design a controller $U(x,y)$, which could make the system (2) and system (3) to achieve an equal and opposite anti-synchronization.

3 Design of adaptive sliding mode controller

In order to obtain the designed form of the controller, we first suppose is the error vector. Thus, its error system is

$$\begin{aligned} D^\beta e &= (A+\Delta A)e+f(y)-f(x)+U(x,y)\\ &= (A+\Delta A)e+F(x,y)+U(x,y)\end{aligned}, \tag{4}$$

where $F(x,y)=f(y)-f(x)$.

Here, we chose a switch sliding surface as $S(t)=D^{\beta-1}e(t)-\int_0^t(A+K)e(\tau)d\tau$, where K is a designed parameter matrices. Usually, the two conditions $S(t)=0$ and $\dot S(t)=0$ are must satisfied simultaneously.

Because $\dot S(t)=0$, we can get

$$\dot S(t)=D^\beta e(t)-(A+K)e(t)=0. \tag{5}$$

Thus, taking Eq. (4) into (5), we can get $\dot S(t)=(\Delta A-K)e(t)+F(x,y)+U(x,y)=0$.

To meet the conditions of sliding mode, we set $DS(t)=-p*sign(S)-r*abs(S)^{m/n}*sign(S)$, in which $sign(S)=\begin{cases}+1, S>0\\ 0, S=0\\ -1, S<0\end{cases}$, $p>0$, $r>0$ are both Controller gain.

On the sliding surface, because $Ds(t)=\dot s(t)=0$ is satisfied, the controller is

$$U(x,y)=(K-\Delta A)e(t)-F(x,y)-(rS+psignS). \tag{6}$$

Theorem 2: When the controller (6) is applied to the system (3), the system (2) and system (3)can achieve the anti-synchronization. In other words, the error system is zero, and it reaches absolute stability.

Proof: When the system is running on the sliding surface, namely $S(t)=0$, the error system can be simplified as $D^\beta e=(A+K)e$.

According to Theorem 1, as long as $(A+K)$ meets the condition $|\arg(\lambda_i)|>q\pi/2$, the error system is stable absolutely.

Therefore, the theorem 2 has been proved.

Lemma 1: If the parameters of the fractional order system is determined, i.e $\Delta A=0$, the controller is still valid, and also can control the drive and response system to achieve anti-synchronization.

Lemma 2: If the order α of drive system and β of response system is not equal, then it needs to introduce a compensation controller $U_I(x,y)=D^\beta(\chi x)-f(x)-(A+\Delta A)\chi x$. So, the controller (6) is still valid.

Lemma 3: If the error system is configured as $e=y-x$, this means synchronization of the drive system and the response, and the controller is still valid.

4 Numerical simulations

We consider the Lorenz system as the drive system $\begin{cases}D^{\alpha_1}x_1=a(y_1-x_1)\\ D^{\alpha_2}y_1=bx_1-x_1z_1-y_1\\ D^{\alpha_3}z_1=x_1y_1+cz_1\end{cases}$ and response system $\begin{cases}D^{\beta_1}x_2=a(y_2-x_2)\\ D^{\beta_2}y_2=bx_2-x_2z_2-y_2\\ D^{\beta_3}z_2=x_2y_2+cz_2\end{cases}$, where the parameters (a, b, c) = (10, 28, 8/3), $\alpha=\beta=0.99$, and the initial value (x_1, y_1, z_1) = (1, 0, 9), (x_2, y_2, z_2) = (1, 1, 1).

We set the parameters are p=0.2, r=6, m=3and n=2;

Coefficient matrix of the system is $A=\begin{pmatrix}-10 & 10 & 0\\ 28 & -1 & 0\\ 0 & 0 & -8/3\end{pmatrix}$;

parameter matrix $K=\begin{pmatrix}-20 & 20 & 0\\ -28 & 0 & 0\\ 0 & 0 & -1/3\end{pmatrix}$. Thus, A + K are $A+K=\begin{pmatrix}-40 & 40 & 0\\ -10 & -1 & 0\\ 0 & 0 & -3\end{pmatrix}$, and its eigenvalues are $(\lambda_1,\lambda_2,\lambda_3)=(-20.5+4.44i,-20.5-4.44i,-3)$.

According to Theorem 1, it satisfies $|\arg(\lambda_i)|>\beta_i\pi/2=0.99\pi/2$, so the error system is absolutely stable, which means the drive system and response system achieve to synchronization. Therefore, the expression of the controller is

$$\begin{cases} u &= (-30e_1+30e_2)-(5s_1+0.2sign(s_1))\\ u &= -38e_1-(5s_2+0.2sign(s_2))\\ u &= -\tfrac{1}{3}e_3-(5s_3+0.2sign(s_3)) \end{cases}.$$

The fractional order nonlinear system equation can be solved by using Adams-Bashforth-Moulton algorithm. So, the iterative formula of solving fractional Lorenz system is

$$\begin{cases} x_{n+1}=x_0+\dfrac{h^\alpha}{\Gamma(\alpha+2)}\left\{10[y^p_{n+1}-x^p_{n+1}]+\sum_{j=0}^{n}a_{1,j,n+1}10(y_j-x_j)\right\}\\ y_{n+1}=y_0+\dfrac{h^\beta}{\Gamma(\beta+2)}\left\{-x^p_{n+1}z^p_{n+1}+(24-4c)x^p_{n+1}+cy^p_{n+1}\right\}\\ \qquad +\sum_{j=0}^{n}a_{2,j,n+1}\left(-x_jz_j+(24-4c)x_j+cy_j\right)\\ z_{n+1}=z_0+\dfrac{h^\gamma}{\Gamma(\gamma+2)}\left\{[x^p_{n+1}y^p_{n+1}-\dfrac{8z^p_{n+1}}{3}]+\sum_{j=0}^{n}a_{3,j,n+1}\left(x_jy_j-\dfrac{8z_j}{3}\right)\right\} \end{cases},$$

in which

$$\begin{cases} x^p_{n+1}=x_0+\dfrac{1}{\Gamma(\alpha)}\sum_{j=0}^{n}b_{1,j,n+1}10(y_j-x_j)\\ y^p_{n+1}=y_0+\dfrac{1}{\Gamma(\beta)}\sum_{j=0}^{n}b_{2,j,n+1}(-x_jz_j+(24-4c)x_j+cy_j)\\ z^p_{n+1}=z_0+\dfrac{1}{\Gamma(\gamma)}\sum_{j=0}^{n}b_{3,j,n+1}\left(x_jy_j-\dfrac{8z_j}{3}\right) \end{cases}$$

and

$$\begin{cases} b_{1,j,n+1}=\dfrac{h^\alpha}{\alpha}((n-j+1)^\alpha-(n-j)^\alpha, 0\le j\le n\\ b_{2,j,n+1}=\dfrac{h^\beta}{\beta}((n-j+1)^\beta-(n-j)^\beta, 0\le j\le n\\ b_{3,j,n+1}=\dfrac{h^\gamma}{\gamma}((n-j+1)^\gamma-(n-j)^\gamma, 0\le j\le n \end{cases},$$

$$\begin{cases} a_{1,j,n+1}=\begin{cases} n^\alpha-(n-\alpha)(n+1)^\alpha & j=0\\ (n-j+2)^{\alpha+1}+(n-j)^{\alpha+1}-2(n-j+1) & 0\le j\le n\end{cases}\\ a_{2,j,n+1}=\begin{cases} n^\beta-(n-\beta)(n+1)^\beta & j=0\\ (n-j+2)^{\beta+1}+(n-j)^{\beta+1}-2(n-j+1) & 0\le j\le n\end{cases}\\ a_{3,j,n+1}=\begin{cases} n^\gamma-(n-\gamma)(n+1)^\gamma & j=0\\ (n-j+2)^{\gamma+1}+(n-j)^{\gamma+1}-2(n-j+1) & 0\le j\le n\end{cases} \end{cases}.$$

Programming numerical analysis with Matlab, we can get time-domain diagram as shown in Fig. 1 and error map as shown in Fig. 2, which demonstrates drive system and response system of Lorenz system achieve anti-synchronization. From the Fig. 1 and Fig. 2, we know the system quickly achieve to anti-synchronization, and the corresponding anti-synchronization error is 0.

5 Conclusions

In this paper, anti-synchronization of a class of fractional-order chaotic system with uncertain parameters is realized based on Sliding Mode Control Theory. Moreover, taken Lorenz system as an example, a detailed iterative formula of computer numerical simulation based on Adams-Bashforth-Moulton Algorithm is proposed, and the simulation results are presented. We can draw the following conclusions:

(1) This method has good robustness, and can well control a class of chaotic system with uncertain parameter to achieve anti-synchronization;

(2) From the three Lemmas, we can also get that this method is also suitable to chaotic system with certain parameters, unequal fractional orders;

(3) The feasibility of fractional order numerical simulation is also been proved.

Abstract

This paper presents a validation assessment method to measure the discrepancies between the model predictions and experimental observations under both aleatory and epistemic uncertainty. The model inputs considered in the paper are sparse point data or interval data, which leads to uncertain parameters for the distribution of the model inputs. A likelihood based method is used to represent the stochastic model inputs and it yields a single probability distribution which integrates the aleatory and epistemic uncertainty of model inputs. This representation of model inputs provides an advantage in computation efficiency for the conventional double loop sampling requirement in uncertainty propagation is collapsed into a single loop sampling. An area based validation metric is extended to compare the probabilistic model predictions obtained from uncertainty propagation with the empirical distribution function of the experimental observations, it reflects an objective quantification of the entire discrepancies between predictions and observations. The confidence interval for the validation metric, which just depends on the amount of experimental observations and confidence level is also developed. A numerical example is used to illustrate the proposed method.

Keywords: validation assessment; likelihood based method; validation metric; confidence interval

1 Introduction

Model based computer is applied in various engineering disciplines, examples range from nuclear reactor certification to understanding of the cosmos. The uncertainty and confidence in model prediction are attracting attention increasingly. Model validation has been advocated as a necessary procedure when the model is used for risk assessment with high consequence systems [1-3]. The fundamental concept of model validation has been intensively argued by professional committees [4-8], and the consensus among researchers is that a rigorous model validation should explicitly account for various uncertainties. The uncertainties can be broadly classified into aleatory and epistemic. For instance, a precise probability distribution indicates the aleatory uncertainty, and the probability distribution with uncertain parameters implies the existence of epistemic uncertainty. This paper concerns the question of how to measure the discrepancies between the model predictions and experimental observations under both aleatory and epistemic uncertainty. The question is usually called "validation assessment" [3], it is a basic process in model validation procedure, the performance of the model can be judged from the measurement.

Several approaches have recently been suggested for validation assessment, including significance testing [9-14], Bayesian method [9, 13, 14], mean based comparison [3, 15, 16] and area based method [17]. All of these approaches have drawbacks. For example, the significance testing to validation is primarily focused on identifying the evidence against a certain hypothesis, and the Bayesian method is mostly focused on the belief that the model is correct. They are rather different from the goal of validation assessment, which is interested in the objective quantification of model accuracy. Instead of making a "accept" or "reject" statement with hypothesis, the mean-based comparison method measures distance between the mean of model predictions and the estimated mean of experimental observations. The limitation of this method is that it only takes the central tendency of predictions and observations into account, while the distribution of predictions contain amount of detail which may be represented insufficiently with a comparison of means. With the aim of measuring the discrepancies of the entire distributions between predictions and observations, the area based method uses the area between the prediction distribution and the observation distribution as a validation metric, but it does not provide a confidence level of the metric due to the lack of sufficient observations. Besides, of the aforementioned drawbacks, there is a serious limitation about theses method that they are only suitable for validation assessment under aleatory uncertainty, and cannot be used directly when model inputs are quantities with epistemic uncertainty.

Typical epistemic uncertainty regarding a model input can be a stochastic quantity with uncertain distribution parameters [18], this is usually due to sparse point data or interval data. Several methods such as evidence theory [19], second order probability method [20], fuzzy sets [21], etc. have been proposed for quantification of the epistemic uncertainty, but the results of these methods which are usually in forms of distribution bounds cannot

* ***Corresponding author*** e-mail swjtu_zhaoliang@126.com

be used in validation assessment directly. This paper extends the area-based validation assessment method to account for epistemic uncertainty arising from sparse or interval data with model inputs. A likelihood based approach [22] is used to construct a single probability distribution for model inputs with uncertain distribution parameters. With the likelihood based representation of uncertainty, the model predictions can be characterized as a single probability distribution after uncertainty propagation, it facilitates the comparison between model predictions and probabilistic experimental observations that are the essential of area based validation metric. The confidence interval of the validation metric is provided by calculating the infimum and supremum of the discrepancy between the cumulative probability distribution function (CDF) of model predictions and the possible experimental empirical distribution functions (EDF) which are bounded by the Kolmogorov - Smirnov limit theorem.

The paper is organized as follows. Section 2 describes the likelihood based method to represent the epistemic uncertainty with an unique probability distribution for model inputs. Section 3 derives the validation metric based on area method, accounting for both aleatory and epistemic uncertainty. Furthermore, this section presents a confidence interval for the validation metric, the interval is associated with the amount of experimental observations. Section 4 demonstrates the proposed method with a numerical example. Finally, Section 5 offers some concluding remarks.

2 Likelihood based representation of epistemic uncertainty

Consider model input X that has a probability density function (PDF) $f_X(x|\boldsymbol{P})$ where $\boldsymbol{P}$ denotes the distribution parameters. With the distribution type is known, the PDF is conditioned on the choice of $\boldsymbol{P}$. The likelihood function $L(\boldsymbol{P})$ is defined as the probability of observing data x given $\boldsymbol{P}$ [22]. When the information regarding X is available with independent point data x_i(i=1,2,⋯,n), the likelihood for $\boldsymbol{P}$ can be calculated as Eq.(1) with a finite precision ε:

$$\begin{aligned} L(\boldsymbol{P}) &\propto \prod_{i=1}^{n} P_i\left(X \in (x_i-\varepsilon, x_i+\varepsilon) \mid \boldsymbol{P}\right) \\ &= \prod_{i=1}^{n} \int_{x_i-\varepsilon}^{x_i+\varepsilon} f_X(x \mid \boldsymbol{P})\mathrm{d}x \\ &\propto \prod_{i=1}^{n} f_X(x_i \mid \boldsymbol{P}) \end{aligned} \quad . \tag{1}$$

Here the independence assumption in Equation (1) is modest in statistical analysis.

Since the likelihood in Equation (1) is actually integrated in an infinitely small interval instead of calculating at data points, it is straightforward to apply the definition to X in the form of interval. When the information regarding X is available with intervals [a_i, b_i] (i=1,2,⋯,m), the likelihood for $\boldsymbol{P}$ of PDF $f_X(x|\boldsymbol{P})$ can be expressed as:

$$\begin{aligned} L(\boldsymbol{P}) &\propto \prod_{i=1}^{m} P_i\left(X \in (a_i, b_i) \mid \boldsymbol{P}\right) \\ &= \prod_{i=1}^{m} \int_{a_i}^{b_i} f_X(x \mid \boldsymbol{P})\mathrm{d}x \end{aligned} \quad . \tag{2}$$

Accounting for both point values and intervals in the available data, the likelihood function of $\boldsymbol{P}$ can be represented as:

$$L(\boldsymbol{P}) \propto \left[\prod_{i=1}^{n} f_X(x_i \mid \boldsymbol{P})\right]\left[\prod_{i=1}^{m} \int_{a_i}^{b_i} f_X(x \mid \boldsymbol{P})\mathrm{d}x\right]. \tag{3}$$

It is popularly known that the $\boldsymbol{P}$ can be estimated by maximizing the likelihood function. However, the validation assessment is interested in the usage of entire likelihood function to construct the PDF of $\boldsymbol{P}$ rather than maximizing the likelihood. Thereby, consider the joint probability density of distribution parameters $\boldsymbol{P}$, denoted by $f_P(\boldsymbol{P})$, it can be calculated as Equation (4) using Bayes theorem with an uniform prior PDF $f_P'(\boldsymbol{P})=h$ (over the whole range of $\boldsymbol{P}$).

$$f_{\boldsymbol{P}}(\boldsymbol{P}) = \frac{L(\boldsymbol{P})h}{\int L(\boldsymbol{P})h\mathrm{d}\boldsymbol{P}} = \frac{L(\boldsymbol{P})}{\int L(\boldsymbol{P})\mathrm{d}\boldsymbol{P}}. \tag{4}$$

After calculating the $f_P(\boldsymbol{P})$, the PDF for X can be constructed based on principles of conditional probability and total probability, as represented in Equation (5).

$$f_X(x) = \int f_X(x \mid \boldsymbol{P}) f_{\boldsymbol{P}}(\boldsymbol{P})\mathrm{d}\boldsymbol{P}. \tag{5}$$

Let Y denotes the model predictions, the PDF of Y represented by $f_Y(y)$ can be obtained using uncertainty propagation analysis. The single PDF of X facilitates the uncertainty propagation for it requires just one level of Monte Carlo sampling to construct the $f_Y(y)$. In contrast, the conventional uncertainty quantification methods such as second order probability method [20] require a two level Monte Carlo sampling: first, draw samples of $\boldsymbol{P}$ from $f_P(p)$, each of them determines a PDF of X: $f_X(x|\boldsymbol{P})$; second, several samples from each $f_X(x|\boldsymbol{P})$ are drawn to calculate a distribution of Y, the process generates a family of $f_Y(y)$ for different $\boldsymbol{P}$ ultimately. The two level Monte Carlo sampling strategy is so computationally costly that it might not always be affordable in practical model application. Furthermore, the family of model output distributions leads to a difficulty in measuring discrepancies between model predictions and experimental observations. The $f_X(x)$ in Eq.(5) can be interpreted as the expected value of $f_X(x|\boldsymbol{P})$, which depends on the choice of $\boldsymbol{P}$. The two level of uncertainties considered in second order probability method are integrated into the single PDF $f_X(x)$, and it can be evaluated numerically. Based on the single PDF for

model input, the $f_Y(y)$ can be calculated using a straightforward Monte Carlo method. The resultant single PDF for model prediction brings an advantage in validation assessment. The following section implements the area based method [17] to measure the discrepancies between model predictions and experimental observations. With the likelihood based method explained in section 2, the area based method can account for both aleatory uncertainty and epistemic uncertainty in validation assessment.

3 Validation assessment using area based method

3.1 AREA METRIC

The aforementioned model prediction can be characterized as a CDF, represented as $F_Y(y)$. Consider the experimental observations are provided as a set of point data y_i, (i=1,2,⋯), the EDF for the data set is represented as $S(y)$, it preserves almost all statistical information in the data set The area based method proposed by Ferson [18] uses the area between the $F_Y(y)$ and the $S(y)$ as the measurement of the discrepancies. The mathematical expression for the area metric can be written as Equation (6):

$$d\left(F_Y, S\right) = \int_{-\infty}^{+\infty} \left|F_Y(y) - S(y)\right| \mathrm{d}y \,, \tag{6}$$

The $d(F_Y, S)$ in Eq.(6) is essentially a special case of the Wasserstein distance. The important merit of the area metric is that $d(F_Y,S)$ measures the discrepancies between the entire distributions from predictions and observations. Since the epistemic uncertainty and aleatory uncertainty in the model inputs have already been quantified with the single PDF $f_X(x)$, the area based method which makes use of the $f_X(x)$ can be applicable in the validation assessment with both epistemic uncertainty and aleatory uncertainty.

3.2 CONFIDENCE INTERVAL FOR THE AREA METRIC

Consider the sample uncertainty in experimental observations, the Kolmogorov-Smirnov statistics can be used to bound the EDF of observations as Equation (7):

$$\begin{aligned} \overline{S}(y) &= \min(1, \max(0, S(y) + D)) \\ \underline{S}(y) &= \min(1, \max(0, S(y) - D)) \end{aligned}, \tag{7}$$

Where $\overline{S}(y)$ and $\underline{S}(y)$ refer to the upper bound and lower bound of the experimental EDF respectively, and the D denotes the critical value for the Kolmogorov-Smirnov statistic [23], it just depends on the confidence level and the amount of experimental observations. After calculating the $\overline{S}(y)$ and $\underline{S}(y)$ with specified confidence level (1-α)×100%, the confidence interval for the area metric can be expressed as Equation (8):

$$\left[\inf_{S(y)\in K} \int_{-\infty}^{+\infty} \left|F_Y(y) - S(y)\right| \mathrm{d}y, \sup_{S(y)\in K} \int_{-\infty}^{+\infty} \left|F_Y(y) - S(y)\right| \mathrm{d}y \right] , \tag{8}$$

where inf denotes the infimum, sup denotes the supremum, and the K represents the region encompassed by $\overline{S}(y)$ and $\underline{S}(y)$, it contains all possible EDFs of the experimental observations. The task of calculating the infimum or supremum taking the amount of experimental observations into account is sometimes challenging, intelligence optimization algorithms such as genetic algorithm can be used to handle this problem. The genetic algorithm randomly generates a population of possible experimental EDF constrained by Equation (7), then evaluates the fitness of each EDF using the area metric. For the infimum calculation task, a small area between possible EDF and model prediction CDF indicates high fitness for this EDF, whereas the supremum calculation task pursues large area as high fitness. The set of parents forming the next generation can be selected based on the fitness of individual EDF, where the high fitness members have more chances of being chosen. The mutation and crossover operation are applied to the parents to create next generation of possible experimental EDF. The selection, mutation and crossover are repeated until the maximum fitness in the population meets the criterion.

The area metric provides a quantitative measurement of the discrepancies between model predictions and experimental observations. The choice of the threshold for the metric is another question in model validation, which is usually called “adequacy decision” [3]. The adequacy decision considers that whether the validation metric is “great” enough to draw a conclusion that the discrepancies are significant. This question is derived from the concept that the threshold should be separated from the validation metric [9, 16, 17]. If the area metric is presented below the chosen threshold, one can conclude that the model is adequate for the intended use. Furthermore, consider the sampling uncertainty of the experimental observations, the upper bound of the confidence interval for area metric can be used to compare with the threshold, it claims that whether the model is adequate with (1-α)×100% confidence. Usually, the threshold quite depends on the intended use of the model for different requirement of model accuracy. Note that the distribution of model predictions calculated on the basis of $f_X(x)$ is not parametrically available, and the value of $d(F_Y,S)$ is expressed in physical units rather than statistical units. It implies that the engineers or project managers may be more rational than the mathematicians who developed the validation assessment method to decide the choice of the threshold. As stated in section 1 earlier, the paper concerns only the question of how to measure the discrepancies between the model predictions and experimental observations, the choice of the threshold for the metric is out of the research scope.

4 Numerical example studies

A numerical example is presented in this section to illustrate the proposed validation assessment method. Consider a material layer slab with thickness L, volumetric heat capacity ρC and thermal conductivity k, it is exposed to a heat flux, the temperature (T) at a specified time (t) after exposure to the heat flux (q) needs to be predicted. The model for the temperature prediction can be written as:

$$T(k,\rho C,T_0,L,q;l,t) = T_0 + \frac{qL}{k}\left[\frac{kt/\rho C}{L^2} + \frac{1}{3} - \frac{l}{L} + \frac{l^2}{2L^2} - \sum_{n=1}^{6}\frac{2}{\pi^2 n^2}\exp\left(-\frac{n^2\pi^2 kt}{L^2\rho C}\right)\cos\left(n\pi\frac{l}{L}\right)\right], \quad (10)$$

where T_0 is the initial ambient temperature, it is fixed at 25°C, l is the location within the material. The controllable inputs (L, q) are assumed to be known exactly, i.e. L=0.0127m, q=1000W/m^2, while the (ρC, k) are uncertain inputs. For the sake of illustration, suppose that the probability distribution of the volumetric heat capacity ρC and thermal conductivity k are described as normal by experts but with uncertain distribution parameters. The observations of ρC are available as three point data {4.52E+05J/m^3°C, 4.10E+05J/m^3°C, 4.02E+05 J/m^3°C}, and the data about k is available in the form of intervals as [0.0601W/m°C, 0.0604W/m°C], [0.0545 W/m°C, 0.0547W/m°C]. Let the purpose of the model be to predict the temperature at the surface of the layer (l=0m) after exposure to the heat flux for 500 seconds (t=500s). Experiment in the circumstance consistent with the intended use of the model is carried out four times repeatedly, the observations are four point data as {210.6°C, 214.6°C, 186.9°C, 219.0°C}. It is required to measure the discrepancies between the model predictions and experimental observations.

Consider that model inputs ρC and k are described with epistemic uncertainty, the likelihood based approach explained in section 2 is used to represent the two model inputs with single probability distribution respectively. Note that the normal distribution describing the model inputs ρC and k is parameterized by mean and standard deviation, so the likelihood in Equation (3) is integrated for the mean and the standard deviation together. The entire admissible ranges for the mean and the standard deviation are both $(0,+\infty)$, for the sake of calculation, here we draw finite bounds for the two ranges. For instance, assume that the mean of ρC can vary in (2.5E+05, 5.5E+05). Based on the observations we believe the finite ranges are still wide enough to cover any possible value of the distribution parameters. By combining Equation (4) and (5), the distributions of the ρC and k are calculated as it is shown in Figure 1 and Figure 2.

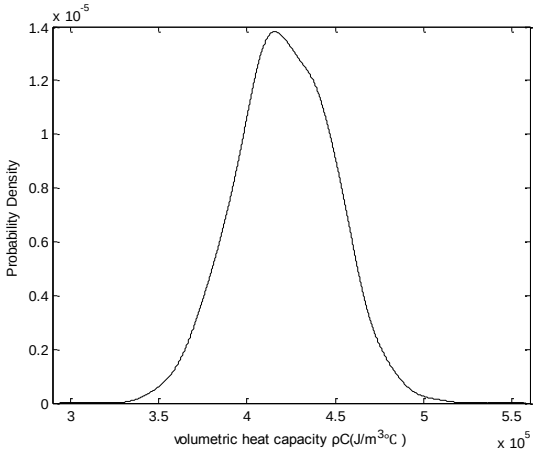

FIGURE 1 Distribution of volumetric heat capacity ρC

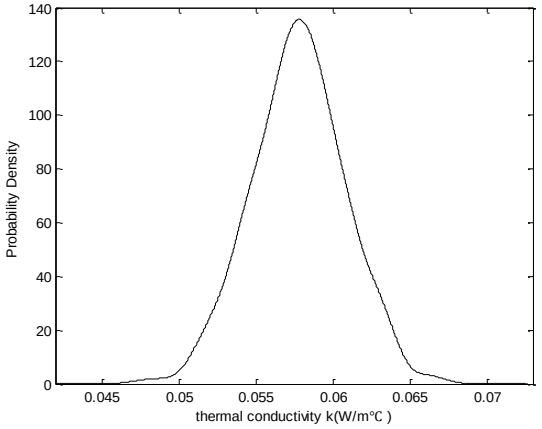

FIGURE 2 Distribution of thermal conductivity k

The distributions presented in Figure 1 and Figure 2 include both epistemic uncertainty and aleatory uncertainty in ρC and k. Note that the integration in Equation (5) is calculated numerically for $f_P(\boldsymbol{P})$ is not parametrically available, so the resultant PDFs for ρC and k are not analytical. An Monte Carlo method is used to propagate the uncertainty of ρC and k through the thermal model in Equation (9), the PDF of the material layer surface temperature at t=500s is shown in Figure 3.

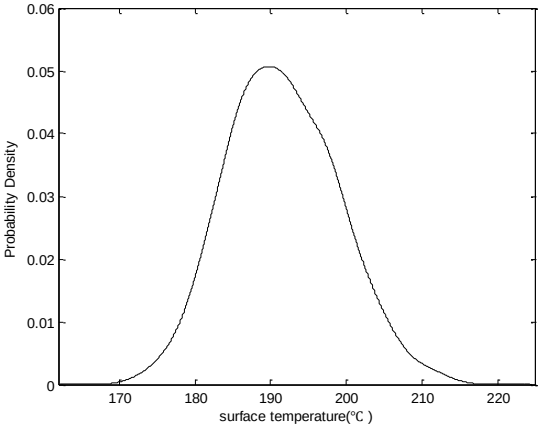

FIGURE 3 Distribution of model predictions

The area metric is used to measure the discrepancies between model predictions and experimental observations. Figure 4 illustrates this area with shaded region between smooth black curve and blue step function. The black curve is the CDF of the model predictions, and the blue step function is the EDF for experimental observations consisting of four point value.

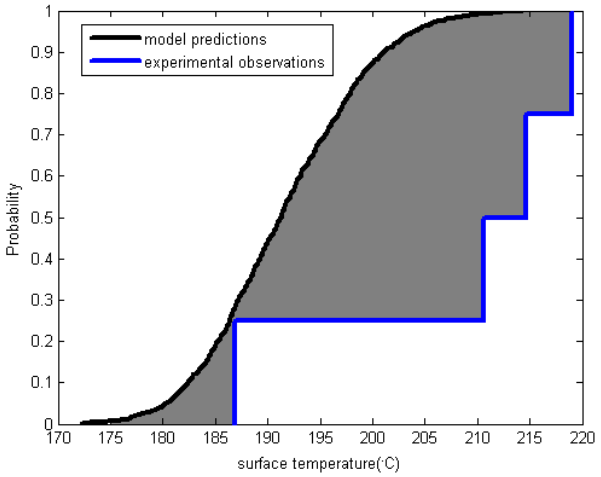

FIGURE 4 EDF of experimental observations against CDF of model predictions

Using Equation (6), the area metric is obtained to be 16.21ºC. A genetic algorithm is employed to find the infimum and supremum defined in Equation (8) to get the confidence interval for the area metric. The exact value of the confidence interval with 95% confidence level is [4.13ºC, 26.88ºC]. The result of the validation assessment provides an objective quantification of the discrepancies between model predictions and experimental observations. As stated early, the threshold for the metric depends on the specific requirement of model accuracy. Here for the sake of illustration, assume the threshold for the discrepancies is 2ºC. Since the lower bound of the metric's confidence interval is beyond the threshold, we can conclude with 95% confidence that the accuracy of the model is insufficient, it indicates that the model needs to be improved.

5 Conclusions

This paper presents a framework for validation assessment when there is both aleatory and epistemic uncertainty in model inputs. The likelihood based method is applied to representation of stochastic quantities with uncertain distribution parameters which are due to sparse point data or interval data. The method's result for an uncertain model input is a single probability distribution that facilitates the following uncertainty propagation and validation metric. It provides an obvious advantage in computation efficiency for the conventional double loop sampling strategy is collapsed into a single loop sampling. The probability distribution of model output obtained from uncertainty propagation is compared with the EDF of experimental observations using area based validation metric, it reflects an objective quantification of the entire discrepancies between predictions and observations. A confidence interval for the validation metric which just depends on the amount of experimental observations and confidence level is also developed. It is helpful for the decision making which follows the validation assessment. The numerical example demonstrates the validation assessment framework presented in this paper.

The discussion of the framework in this paper is limited to the univariate case, which implies the model output to be a single response quantity following a statistical distribution. The validation assessment also looks for a metric, which have the flexibility of measuring the discrepancies between predictions and observations in a multivariate case. There are several types of multivariate case such as multiple location for model response or various response quantities at a single location. The validation metric for the multivariate case is required to provide an overall performance measurement for the model. There are still difficulties in aggregating individual metrics accounting for confidence level and correlation among multiple quantities. Future work in this direction will extend the validation assessment to multivariate case.

Fuzzy set and rough set based evaluation algorithm of web customers

Yun Peng*

Computer and Information Engineering College, Jiangxi Normal University, Nanchang 330022, China

Received 1 July 2014, www.cmnt.lv

Abstract

A fuzzy algorithm of web customers evaluation based on rough set is presented. Key attributes can be gotten through rough set. The evaluation from the data objects based on key attributes can reduce the data size and algorithm complexity. After Clustering analysis of customers, then the evaluation analysis will process to the clustering data. There are a lot of uncertain data in customer clusters, so the traditional method of classification and evaluation to the incomplete data is very difficult. Superposition evaluation algorithm based on fuzzy set can improve the reliability and accuracy of web customer evaluation. Evaluation of the web customer also can improve efficiency, service quality and profitability of web businesses.

Keywords: Rough Set, Membership Function, Cluster Analysis, Fuzzy Set

1 Introduction

Following the rapid development of electronic commerce, which brought a huge number of web customer groups, and how to classify and evaluate the customers is very important. According to the customer's transactions, characteristics of the customer information, customers can be classified and evaluated and given the levels. Web services can be improve efficiency in the future based on the actual conduct of targeted customer, and increase customer attention and interest level, thereby enhancing the profitability of web. Because of the ambiguity of customer behaviour, a comprehensive evaluation is designed based on fuzzy superposition algorithm in this paper [1].

2 The proposed algorithm

Customer's attribute can be web transactions based on behaviour characteristics, also it can be static characteristics of the customer, and the attribute can be looked as the basis for cluster analysis. In the classification process, the keywords are divided into different classes for different levels of customer types. Membership function will convert all the data values less than or equal to 1, so the next step of the fuzzy clustering can be carried out [2].

Fuzzy set A in the domain U, with a membership function to describe it, namely: $U \rightarrow [0,1]$, for any $u \in U$, there is $u \rightarrow \mu_{\tilde{A}}(u)$, $\mu_{\tilde{A}}(u) \in [0,1]$, $\mu_{\tilde{A}}(u)$ is the membership of element u to set A, which represents the degree of u belonging to A. The designing of fuzzy superposition evaluation algorithm is shown as follows [3].

(1) Let U be the customer domain, U_i is the No.i customer, $i \in 1,2,3 \ldots n$, A_j is the No.j attribute of U, $j \in 1,2,3 \ldots m$, S_{ij} is the value of U_i and A_j, $P(K_j)$ is the weighting coefficients of A_j. The membership function of keyword property value is shown in (1).

$$\mu_{\tilde{A}}(S_{ij}) = F(S_{ij})/(S_{1j} + S_{2j} \ldots S_{nj}) * P(K_j). \quad (1)$$

After pre-treatment customers, we can design an appropriate fuzzy clustering algorithm of customer data.

(2) Set up the fuzzy similarity relation R of U. The order of R matrix is $|U|$, m is the number of attributes. Using Euclidean distance formula shown in (2), we can calculate the matrix elements of r_{ij} in R [4].

$$r_{ij} = \begin{cases} 1 & i = j \\ \sqrt{\frac{1}{m}\sum_{k=1}^{m}(sik - sjk)^2} & i \neq j \end{cases}. \quad (2)$$

(3) The graph $G = (V, E)$ can be obtained by R, and the maximum spanning tree as $T = (V, TE)$ from G can be calculated using Prim algorithm.

(4) According to the practical problems to set an appropriate $\lambda \in [0,1]$, $T(e)$ is the weight of edge e, if $T(e) < \lambda$, edge e will be removed, the connected component is the classification based on λ.

(5) The set of attributes reduction can be derived from discernibility matrix and discernibility function [5]. Discernibility matrix is shown in (3).

$$M(B) = \{m(i, j) | n \times n, 1 \leq i, j \leq n\}, \quad (3)$$

* ***Corresponding author*** e-mail 332952797@qq.com

where $m(i, j) = \{a \in A \mid a(i) \neq a(j) \text{ and } d(i) \neq d(j)\}$, $n = |U|$.

Discernibility function is shown in (4). Σ is "∨ ", Π is "∧ ".

$$\Delta = \prod_{(i,j)\in U\times U} \sum m(i,j) \quad . \tag{4}$$

(6) Attribute reduction and nuclear can be derived from the minimal disjunctive of distinction function, which can deduce an attributes set of critical evaluation [6].

(7) Set up evaluation set $V = \{v_1, v_2, ...v_m\}$, the weight distribution of U_i is: $\underset{\sim}{A_i} = \{a_{i1}, a_{i2}, \ldots, a_{in_i}\}$. The evaluation factors are the fuzzy mapping from U to $F(V)$ shown in (5).

$$\begin{aligned} &\underset{\sim}{f}: U \to F(V), \forall u \in U \\ &u_i \mapsto \underset{\sim}{f}(u_i) = \frac{r_{i1}}{v_1} + \frac{r_{i2}}{v_2} + \cdots + \frac{r_{im}}{v_m}, \end{aligned} \tag{5}$$

where $0 \le r_{ij} \le 1$, $1 \le i \le n$, $1 \le j \le m$

$\underset{\sim}{R_i}$ is the single factor evaluation matrix of U_i, so the first-class comprehensive evaluation is as follows: $\underset{\sim}{R_i} = \underset{\sim}{A_i} \circ \underset{\sim}{R_i} = (b_{i1}, b_{i2}, ..., b_{im})$, $(i = 1,2, ...s)$.

(8) As an element for each U_i, using $\underset{\sim}{B_i}$ as its single factor assessment, the evaluation matrix can be derived.

(9) According to some property of a higher level, a subset S can be divided into more advanced sub-set, then return step (7) and (8). Finally, we can constitute a multi-class fuzzy evaluation.

3 Example analysis

According to the type of attribute value and the membership function, we can calculate the membership degree of each attribute, and the membership value is as the initial value for classification. Original customer data is shown in Table 1, where C is the customer, CA is the transaction attribute [7].

TABLE 1 Original customer data

C	CA_1	CA_2	CA_3	CA_4	CA_5
C_1	322	524	401	112	123
C_2	121	510	502	142	280
C_3	126	228	224	89	118
C_4	210	217	565	321	217
C_5	260	162	865	212	322
C_6	215	159	625	112	265
C_7	129	195	587	219	285
C_8	139	112	495	120	279
C_9	562	255	750	250	105
C_{10}	409	596	362	201	419

(1) Through the mapping of membership function, data can be initialized shown in Table 2, the values are changed to the values less than or equal to 1, and the values reflect the dependence of the attribute.

TABLE 2 Initialization of customer data

C	CA_1	CA_2	CA_3	CA_4	CA_5
C_1	0.134	0.140	0.401	0.500	0.390
C_2	0.343	0.144	0.300	0.257	0.144
C_3	0.257	0.451	0.500	0.457	0.310
C_4	0.544	0.457	0.400	0.357	0.229

C_{10}	0.245	0.235	0.090	0.093	0.258	0.066	0.042	0.138	0.147

(3) The graph $G = (V, E)$ can be derived by R, and the maximum spanning tree $T = (V, TE)$ from G can be calculated using Prim algorithm, where $|V| = 10$, $|TE| = 9$, the maximum spanning tree is shown in Figure 1.

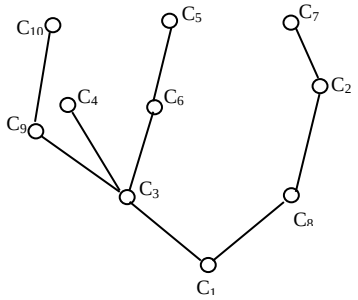

FIGURE 1 The maximum spanning tree

The three clusters above is in accordance with the feature of customers through the data analysis. Sometimes the λ is a variable value, we can draw the dynamic graph by the max-tree. The dynamic classification graph is as Figure 2.

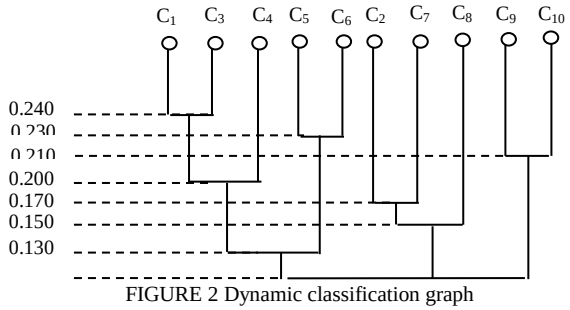

FIGURE 2 Dynamic classification graph

Set $\lambda = 0.130$, customer classification can be obtained as follows:

C1 = {C_1, C_3, C_4, C_5, C_6 }, C2 = {C_2, C_7, C_8}, C3 = {C_9,C_{10}}.

(4) The distinction matrix is shown in Table 4.

TABLE 4 Distinction matrix

	C_1	C_2	C_3	C_4	C_5	C_6	C_7	C_8	C_9
C_1									
C_2	2,5								
C_3	3,4	4,5							
C_4	3	2,4,5	4						
C_5	1,2,3	1,2,3,4	1,3,4	1,2,3,4					
C_6	2,5	1,2,4,5	1,2,4	1,2,4,5	3,4				
C_7	2,4	2,3,5	1,2	1,2	3,4,5	4,5			
C_8	1,2	2,3.4,5	2,4	2,4	1,2,3,4,5	1,2,5	1,2,4		
C_9	2,3,4	1,2,3,5	1,2	1,2	3,4,5	4,5	2	3.4,5	
C_{10}	1,3,4,5	2,3,4,5	2,3,5	1,4,5	1,3	3,4	2,4,5	2,5	1,3,5

According to Table 4, we can get distinction function as follows:

Δ=($CA_2 \vee CA_5$)$\wedge$ ($CA_3 \vee CA_4$)$\wedge$ ($CA_4 \vee CA_5$)$\wedge CA_3 \wedge$ ($CA_2 \vee CA_4 \vee CA_5$)$\wedge CA_4 \wedge$ ($CA_1 \vee CA_2 \vee CA_3$)$\wedge$ ($CA_1 \vee CA_2 \vee CA_3 \vee CA_4$)$\wedge$ ($CA_1 \vee CA_2 \vee CA_3 \vee CA_4$)$\wedge$ ($CA_1 \vee CA_2 \vee CA_4 \vee CA_5$)$\wedge$ ($CA_1 \vee CA_2 \vee CA_4$)$\wedge$ ($CA_2 \vee CA_4$)$\wedge$ ($CA_2 \vee CA_3 \vee CA_5$)$\wedge$ ($CA_1 \vee CA_2$)$\wedge$ ($CA_3 \vee CA_4 \vee CA_5$)$\wedge$ ($CA_2 \vee CA_3 \vee CA_4 \vee CA_5$)$\wedge$ ($CA_1 \vee CA_2 \vee CA_3 \vee CA_4 \vee CA_5$)$\wedge$ ($CA_1 \vee CA_2 \vee CA_5$)$\wedge$ ($CA_2 \vee CA_3 \vee CA_4$)$\wedge$ ($CA_1 \vee CA_2 \vee CA_3 \vee CA_5$)$\wedge CA_2 \wedge$ ($CA_1 \vee CA_3 \vee CA_4 \vee CA_5$)$\wedge$ ($CA_1 \vee CA_4 \vee CA_5$)$\wedge$ ($CA_1 \vee CA_3$)$\wedge$ ($CA_2 \vee CA_5$)$\wedge$ ($CA_1 \vee CA_3 \vee CA_5$)

$=CA_1 \wedge CA_4 \wedge CA_5$

After reduction we can get the key attributes as {CA_1, CA_4, CA_5} and the second layer attribute as {CA_2, CA_3}. A two-tiered evaluation system for fuzzy evaluation can carried out then. To analyse the evaluation system conveniently, we simplify the system accordingly, but does not affect the algorithm analysis [5].

(5) Customer evaluation grades are divided into four grade (excellent, good, middle, bad). The weight of first-class is: $\underset{\sim}{W}$ ={0.30,0.40,0.20,0.10}.

The weight of second-class is:

$\underset{\sim}{W}_1$ ={0.35,0.45,0.20};

$\underset{\sim}{W}_2$ ={0.30,0.25,0.10,0.20,0.15};

$\underset{\sim}{W}_3$ ={0.45,0.30,0.25};

$\underset{\sim}{W}_4$ ={0.32,0.30,0.20,0.18}.

The weight of third-class is:

$\underset{\sim}{W}_{11}$={0.50,0.30,0.20};

$\underset{\sim}{W}_{12}$={0.30,0.20,0.15,0.25,0.10}.

(6) The fuzzy evaluation matrix is shown in (6) and fuzzy evaluation result of second-class is shown in (7).

$$\underset{\sim}{R}_{11} = \begin{bmatrix} 0.25 & 0.45 & 0.20 & 0.10 \\ 0.30 & 0.20 & 0.35 & 0.15 \\ 0.28 & 0.22 & 0.39 & 0.11 \end{bmatrix} \quad (6)$$

$$\underset{\sim}{B}_{11} = \underset{\sim}{W}_{11} \circ \underset{\sim}{R}_{11} = \underset{\sim}{B}_{11}$$

$$\begin{bmatrix} (0.50 \wedge 0.25) \vee (0.30 \wedge 0.30) \vee (0.20 \wedge 0.28) \\ (0.50 \wedge 0.45) \vee (0.30 \wedge 0.20) \vee (0.20 \wedge 0.22) \\ (0.50 \wedge 0.20) \vee (0.30 \wedge 0.35) \vee (0.20 \wedge 0.39) \\ (0.50 \wedge 0.10) \vee (0.30 \wedge 0.15) \vee (0.20 \wedge 0.11) \end{bmatrix} = (0.30,0.45,0.30,0.15),$$

the normalized result is obtained: = (0.25,0.40,0.25,0.10).

Using the same algorithm can be obtained:

$\underset{\sim}{B}_{12}$ = (0.30,0.40,0.20,0.10);

$\underset{\sim}{B}_{13}$= (0.25,0.35,0.20,0.20).

$$\underset{\sim}{B}_1 = \underset{\sim}{W}_1 \circ \underset{\sim}{R}_1 = \begin{bmatrix} (0.35 \wedge 0.25) \vee (0.45 \wedge 0.30) \vee (0.20 \wedge 0.25) \\ (0.35 \wedge 0.40) \vee (0.45 \wedge 0.40) \vee (0.20 \wedge 0.35) \\ (0.35 \wedge 0.25) \vee (0.45 \wedge 0.20) \vee (0.20 \wedge 0.20) \\ (0.35 \wedge 0.10) \vee (0.45 \wedge 0.10) \vee (0.20 \wedge 0.20) \end{bmatrix} = , \quad (7)$$

$$(0.30, 0.40, 0.25, 0.20)$$

The normalized result is obtained:

$\underset{\sim}{B}_1$ = (0.25,0.35,0.25,0.15).

Using the same algorithm can be obtained:

$\underset{\sim}{B}_2$ = (0.25,0.35,0.20,0.20);

$\underset{\sim}{B}_3$ = (0.30,0.45,0.10,0.15);

$\underset{\sim}{B}_4$ = (0.25,0.30,0.20,0.25).

(7) According to the second-class evaluation results matrix, first-class level evaluation shown in (8) can be derived.

$$\underset{\sim}{B} = \underset{\sim}{W} \circ \underset{\sim}{R} = \begin{bmatrix} (0.30 \wedge 0.25) \vee (0.40 \wedge 0.25) \vee (0.20 \wedge 0.30) \vee (0.10 \wedge 0.25) \\ (0.30 \wedge 0.35) \vee (0.40 \wedge 0.35) \vee (0.20 \wedge 0.45) \vee (0.10 \wedge 0.30) \\ (0.30 \wedge 0.25) \vee (0.40 \wedge 0.20) \vee (0.20 \wedge 0.10) \vee (0.10 \wedge 0.20) \\ (0.30 \wedge 0.15) \vee (0.40 \wedge 0.20) \vee (0.20 \wedge 0.15) \vee (0.10 \wedge 0.25) \end{bmatrix} = . \quad (8)$$

$$(0.25, 0.35, 0.25, 0.20)$$

The normalized result: $\underset{\sim}{B}$ = (0.24,0.34,0.24,0.18).

Based on the maximization of fuzzy set membership, the evaluation results of customer class C1 can be rated as “good”.

4 Conclusions

The evaluation of web customers adopts multi-class structure and takes the static and dynamic attributes into account. To delete the redundant attributes and improve the computation efficiency, attributes reduction is necessary. The evaluation result is an important reference for commercial distribution of web businesses. The weight factors and the fuzzy evaluation algorithm can be adjusted according to the actual customer data. In designation of superposition algorithm to evaluate web customers, compliance with requirements of enterprise, true reflection of the needs and behaviour of customers and adaptive algorithm for data processing are all to be considered. Tested by actual data analysis, cluster

analysis can reduce the size of customer data and data noise, and the key class evaluation analysis can improve the evaluation efficiency of web customers.

Abstract

The coordination of production scheduling and transportation has recently received a lot of attention in logistics and supply chain management. We study a coordinated scheduling problem, in which each job is transported to a single serial batching machine for further processing, each batch to be processed occurs a processing cost, and the objective is minimizing the sum of the makespan and the total processing cost. Under the condition of the jobs' processing times are equal, if the job assignment to the vehicles is predetermined, we provide a polynomial time dynamic programming algorithm, for the general problem, we prove it is NP-hard. When the returning time of vehicle is zero, we present the approximation algorithm and prove that the worst case ratio of the algorithm is not greater than $2-\frac{1}{m}$, and the bound is tight.

Keywords: supply chain scheduling, dynamic programming algorithm, complexity, worst case analysis

1 Introduction

The classical scheduling problems usually assume that there is an infinite number of facilities for processing jobs, and the transportation between the warehouse and the facility can be done instantaneously. As a result, the job delivery and the machine scheduling are separately considered without effective coordination between the two. Coordination between job delivery and machine scheduling becomes more practical.

The coordination of production scheduling and transportation has recently received a lot of attention in logistics and supply chain management. Semi-finished jobs are transported from a holding area to a manufacturing facility for further processing by transporters in many manufacturing systems. Another motivation arises in many industries where the coordination of production and transportation can help to save energy and reduce fuel consumption. This is particularly true in the iron and steel industry.

In this paper, motivated by applications in the iron and steel industry, we study a coordinated scheduling problem of transportation and production. The jobs located at a holding area need to be transported by m vehicles to a serial batching machine for further processing. Each vehicle can transported one job at a time, and the serial batching machine can process several jobs at a time. Each batch of jobs to be processed on the serial batching machine occurs a processing cost; assume that batch processing cost is proportional to the batch number. The problem is to find a joint schedule of transportation and production such that the objective is to minimize the sum of makespan and total processing cost.

In the last decade, the coordination of transportation and scheduling has become one of the most important topics in production and operations management research. Chungyee L, Zhilong C [1] considers two types of transportation. The first type is intermediate transportation in a flow shop where jobs are transported from one machine to another for further processing. The second type is the transportation necessary to deliver finished jobs to the customer.

The batching machine scheduling is an important research topic. Recent reviews of batch scheduling research are provided by Potts C N and Kovalyov M Y [2] and Brucker P et al. [3]. The scheduling problems on the batching machine can be divided into two categories of parallel batch and serial batch according to batch processing pattern. In parallel batching scheduling problems, many jobs can be processed on the machines at any time; the processing time of batch is equal to the maximum of all jobs' processing times of this batch. Yuzhong Z, et al. [4] consider single parallel machine scheduling problem which the jobs have the sizes and only two different arrival time, present the approximation algorithm that the worst case ratio is not greater than $\frac{33}{14}$ when the processing times and the sizes are agreeable.

In serial batching scheduling problems, only one job can be processed on the machines at any time, and the

* ***Corresponding author*** e-mail gucunchang@163.com

jobs are processed one by one simultaneously, the processing time of batch is equal to the setup time plus the total processing times of the jobs in this batch. Coffman E G et al. [5] study minimizing the total completion times scheduling problem on single serial batch machine. Liji S et al. [6] consider the serial batch scheduling problem embedded in a job shop environment to minimize makespan, propose a tabu search algorithm which consists of various neighbourhood functions, multiple tabu lists and a sophisticated diversification structure. Glass C A et al. [7] study a problem of scheduling and batching on two machines in a flow-shop and open-shop environment, the aim is to make batching and sequencing decisions, which specify a partition of the jobs into batches on each machine, and a processing order of the batches on each machine, respectively, so that the makespan is minimized. Webster S and Baker K R [8] consider scheduling groups of jobs on a single machine on three basic models known as family scheduling with item availability, family scheduling with batch availability, and batch processing. Baptiste P [9] analyses the single parallel batching and serial batching scheduling problems that all jobs are arrived at time 0, present the dynamic programming algorithms respectively. But, the attention is relatively less for the coordination of transportation and serial batching scheduling at present.

In this paper, we investigate the problem of coordinated scheduling on single serial batching machine with transportation. At time 0, the n jobs $J_1, J_2, \ldots, J_n$ located at a holding area are transported by the m vehicles to a serial batching machine for further processing, the transportation times are $t_1, t_2, \ldots, t_n$, respectively. In the transportation stage, each vehicle can deliver only one job at a time, the transportation time of one job transported by different vehicles is identical, and the empty moving time of each vehicle from the batching machine back to the holding area is t. In the production stage, the processing time of the job J_j is p_j, $j = 1, 2 \ldots, n$, the serial batching machine can process several jobs simultaneously as a batch, the maximum number of jobs that can be processed simultaneously in the serial batching machine is called capacity c of that batching machine, the completion time C_j of any job J_j in each batch is the fixed set-up time s plus the total processing times of the jobs in this batch. Once processing of a batch is initiated, it cannot be interrupted and other jobs cannot be introduced into the machine until processing is completed. Each batch to be processed on the batching machine occurs a processing cost, b is the number of batches to be processed on the batching machine, $\alpha(b)$ is the linear non-decreasing function of b, and denote the processing cost function. The objective is minimizing the sum of the makespan and the total processing cost $C_{\max} + \alpha(b)$. This problem is denoted as $D \to 1 \mid m \geq 1, c \geq 1, s - batch \mid C_{\max} + \alpha(b)$.

The paper is organized as follows. In Section 2, we give some preliminaries and a useful lemma. Section 3 studies a special case, and provides a polynomial time dynamic programming algorithm. In Section 4, we study the complexity of the problem; propose the TSPT-DP algorithm to solve the problem. Finally, some conclusions are made in Section 5.

2 Preliminaries

Let π and π^* be a feasible solution and an optimal solution, respectively. We will use the following notations and definitions frequently in the reminder of this paper.

$b^{\pi}(b^*)$: the total number of batches in $\pi(\pi^*)$.

$B_l^{\pi}(B_l^*)$: the l-th processing batch in $\pi(\pi^*)$, $l = 1, 2, \ldots, b^{\pi}(b^*)$.

$n_l^{\pi}(n_l^*)$: the number of jobs processed up to the l-th batch, clearly, $n_{k^{\pi}}^{\pi} = n_{k^*}^* = n$.

$\mid B_l^{\pi} \mid (\mid B_l^* \mid)$: the number of jobs processed in $B_l^{\pi}(B_l^*)$, clearly, $\mid B_l^{\pi} \mid = n_l^{\pi} - n_{l-1}^{\pi} (\mid B_l^* \mid = n_l^* - n_{l-1}^*)$.

$r_j^{\pi}(r_j^*)$: the arrival time of the job J_j, i.e., the time when J_j arrives at the serial batching machine.

$r_{[j]}^{\pi}(r_{[j]}^*)$: the arrival time of the j-th arrived job.

$S_l^{\pi}(S_l^*)$: the starting time of the batch $B_l^{\pi}(B_l^*)$.

$C_j^{\pi}(C_j^*)$: the completion time of the job J_j.

$C^{\pi}(l)(C^*(l))$: the completion time of the batch $B_l^{\pi}(B_l^*)$, clearly, $C_j^{\pi} = C^{\pi}(l)(C_j^* = C^*(l))$, for $J_j \in B_l^{\pi}(B_l^*)$.

The notations can be abbreviated to $b, n_l, r_j, r_{[j]}, B_l$, $\mid B_l \mid$, et al. Let $n_0 = 0$, then, $C(i) = S_i + s + \sum_{j \in B_i} p_j$, $C_{\max} = C(b) = S_b + s + \sum_{j \in B_i} p_j$. In situation where the dimension on the measurements $C_{\max}$ and $\alpha(b)$ is difficult to unify, we may adjust cost function $\alpha(b)$ to uniform dimension with the maximum completion time. For ease of presentation, denote our problem as TSBSM.

Although the problem considered in this paper is different from that in Hall N G and Potts C N [10], some properties can be found in the same way.

Lemma 1. For problem $D \to 1 \mid m \geq 1, c \geq 1, s - batch, p_j = p \mid C_{\max} + \alpha(b)$, there exists an optimal solution π^* in which:

(i) There is no idle time between the jobs transported on each vehicle in the transportation part.

(ii) All jobs assigned to the same vehicle are scheduled in the non-decreasing order of transportation times.

(iii) The starting time of each batch on the serial batching machine is made either an arrival time of some job on the machine or immediately at a time when the machine becomes available.

(iv) earlier arrived jobs are processed no later than those arrived later.

Usually, the quality of an approximation algorithm (denoted by H) is measured by the worst case ratio of the algorithm, which is defined as the smallest number ρ such that $F^H \le \rho F^*$ for all instances, where F^H and F^* denote the objectives of solution produced by H and the optimal algorithm, respectively.

3 A polynomial time algorithm for a special case

In this section, we consider a special case where the job assignment to the vehicles is predetermined. It is evident that the problem reduces to an optimal serial batching problem in this case. This special case characterizes the practical situation where the arrival times of the jobs are known. Now, we can provide a dynamic programming algorithm to solve the optimal serial batching problem in a polynomial time as follow.

Re-index all jobs $J_j, j = 1,2,\ldots,n$, in accordance with the job arrival time on the serial batching machine, i.e., $r_1 \le r_2 \le \cdots \le r_n$, the processing time p_j of any job J_j on the serial batching machine is p. It suffices to consider one job sequence and apply it to the processing of jobs on the serial machine. So the starting time of each batch on the machine need to be decided, and this can be done by dynamic programming.

By Lemma 1(iii), the starting time S_l of the batch B_l on the serial batching machine is either the completion time $C(l-1)$ of the batch B_{l-1} or the arrival time r_{n_l} of the last arrived job J_{n_l} in this batch. In the first case, $S_l = C(l-1) = S_{l-1} + s + |B_{l-1}|\, p$, let B_j denote the earliest processing batch which the jobs are processed consecutively until the batch B_l, the starting time of the batch B_j must be the arrival time r_{n_j} of the last arrived job J_{n_j} in this batch, so,

$$\begin{aligned} S_l &= r_{n_j} + (l-j)s + (n_l - n_{j-1})p, \\ &= r_{n_j} + (l-j)s + (|B_j| + \cdots + |B_{l-1}|)p. \end{aligned} \quad (1)$$

Denote $n_l - n_{j-1} = q_l$, satisfy $q_l + j \le n$. In the second case, $S_l = r_{n_l}$.

Hence, the possible starting time of the bath B_l on the serial batching machine can be $r_j, r_j + s + xp, \ldots, r_j + zs + yp$, where $\lceil n/c \rceil \le z \le l-1 \le n,\ x \le y \le n-j$, and $S_0 = 0$.

Define $f(k, j, S_l)$ as the minimal makespan to schedule the first k jobs $J_1, J_2, \ldots, J_k$, provided that the current last batch B_l contains jobs $J_j, J_{j+1}, \ldots, J_k$, and starts to be processed at time S_l , where $k - j + 1 \le c,\ S_l \ge r_k$. If we know the available time $f(j-1, i, S_{l-1})$ of the batching machine before process jobs $J_j, J_{j+1}, \ldots, J_k$, then the starting time of the batch B_l is actually fixed, i.e., $S_l = \max\{f(j-1, i, S_{l-1}), r_k\}$.

$f(k, j, S_l)$ satisfies the following three properties:

(i) $0 < k - j + 1 \le c$;

(ii) $S_l = r_j, r_j + s + xp, \ldots, r_j + zs + yp$, and $S_l - S_{l-1} \ge s + p, l = 2,3,\ldots,b$, where $x \le y \le n$, $\lceil n/c \rceil \le z \le l-1$;

(iii) $\lceil k/c \rceil \le l \le k$.

Otherwise, $f(k, j, S_l) = \infty$.

Dynamic Programming Algorithm *DP*

Initial condition:

$f(0,0,0) = 0$;

Recursive relation:

$f(k, j, S_l) = \min\{\max\{f(j-1, i, S_{l-1}), r_k\} + (s + (k-j+1)p) \mid$ all possible states $(i, S_{l-1})\}$,where $j-1, i, S_{l-1}$ satisfy the three condition described above.

Optimal solution:

$F(n) = \min\{f(n, j, S_b) + \alpha(b) \mid$ all possible states $(j, S_b)\}$.

By recording all the necessary information in the above process, an optimal schedule can be calculated. It is not difficult to see that the time complexity of the algorithm *DP* is $O(cn^4)$. The following theorem can be obtained.

Theorem 1. Algorithm *DP* finds an optimal schedule for problem $D \to 1 \mid m \ge 1, c \ge 1, s - batch, p_j = p \mid C_{\max} + \alpha(b)$ in $O(cn^4)$ time when the job assignment to the vehicles is predetermined.

We now demonstrate the above solution method with a numerical example.

Example. Job set $J = \{J_1, J_2, J_3, J_4\}$, $m = 2, t = 1, c = 3$, $t_1 = 1, t_2 = 4, t_3 = 2, t_4 = 1, s = 1, p = 2, \alpha(b) = 5b$, assume that J_1 and J_2 are transported by one vehicle, J_3 and J_4 are transported by another vehicle. From the above method, we know $r_1 = 1, r_2 = 2, r_3 = 4, r_4 = 6$.

We have the following results by the dynamic programming algorithm *DP* :

$f(1,1,S_1) = \max\{f(0,0,0), r_1\} + (s+p) = 4$;

$f(2,1,S_1) = \max\{f(0,0,0), r_2\} + (s+2p) = 7$;

$f(2,2,S_2) = \max\{f(1,1,S_1), r_2\} + (s+p) = 7$;

$f(3,1,S_1) = \max\{f(0,0,0), r_3\} + (s+3p) = 11$;

$f(3,2,S_2) = \max\{f(1,1,S_1), r_3\} + (s+2p) = 9$;

$f(3,3,S_2)=\max\{f(2,1,S_1),r_3\}+(s+p)=10$;
$f(3,3,S_3)=\max\{f(2,2,S_2),r_3\}+(s+p)=10$;
$f(4,2,S_2)=\max\{f(1,1,S_1),r_4\}+(s+3p)=13$;
$f(4,3,S_2)=\max\{f(2,1,S_1),r_4\}+(s+2p)=12$;
$f(4,4,S_2)=\max\{f(3,1,S_1),r_4\}+(s+p)=14$;
$f(4,3,S_3)=\max\{f(2,2,S_2),r_4\}+(s+2p)=12$;
$f(4,4,S_3)=\min\{\max\{f(3,2,S_2),r_4\}+(s+p)=12,\ \max\{f(3,3,S_2),r_4\}+(s+p)=13\}=12$;
$f(4,4,S_4)=\max\{f(3,3,S_3),r_4\}+(s+p)=13$;
$F(4)=\min\{f(4,j,S_b)+\alpha(b)\mid \text{all possible states } (j,S_b)\}=f(4,3,S_2)+\alpha(2)=22$.

The optimal schedule on the serial batching machine is finally found as $\pi^*=\{\{J_1,J_3\},\{J_4,J_2\}\}$ with the optimal objective value of 22.

4 Complexity and approximation algorithm

In this section, we firstly show that for TSBSM is NP-hard by reducing the 2-Partition problem to the decision version of this problem when the job assignment to the vehicles is not predetermined, secondly propose an approximation algorithm for the problem TSBSM.

4.1 COMPLEXITY

2-Partition problem: Given $h+1$ positive integers a_j, $j=1,2,\ldots,h$, and a, such that $\sum_{i=1}^{h}a_j=2a$. The question asks if the set $H=\{1,2,\ldots,h\}$ can be divided into two disjoint subsets G_1 and G_2, such that $G_1+G_2=H$, $\sum_{j\in G_1}a_j=\sum_{j\in G_2}a_j=a$.

Theorem 2. The problem $D\to 1\mid m\ge 1,c\ge 1,s-batch, p_j=p\mid C_{\max}+\alpha(b)$ is NP-hard even if $m=2$.

Proof. To any instance of the 2-Partition problem, we construct an instance of TSBSM as follow. There are $n=2h$ jobs split into two job sets: the J'-jobs (partition jobs) denoted by $J_j',j=1,2,\ldots,h$, the J''-jobs (auxiliary jobs) denoted by $J_j'',j=1,2,\ldots,h$. Their transportation times and other parameters are given as follows:

Transportation times: $t_{J_j'}=2a_j,t_{J_j''}=0,j=1,2,\ldots,h$;

Returning time: $t=0$;

Set-up time of the serial batch: $s=a$;

Processing time: $p_j=\frac{a}{h},j=1,2,\ldots,2h$;

Processing cost: $\alpha(b)=3ba$;

Machine capacity: $c=h$;

Threshold value: $y=10a$.

We are going to show that for the constructed scheduling problem instance, a schedule π with $C_{\max}+\alpha(b)\le y$ exists if and only if the 2-Partition problem has a solution.

If there is a solution to the 2-Partition problem instance, we show that there is a schedule π with $C_{\max}+\alpha(b)\le y$ for the scheduling instance. Suppose that the 2-Partition problem instance has a solution G_1 and G_2. Now construct the following schedule π:

Since the transportation times of J''-jobs and the returning time of the vehicles are equal to 0, J''-jobs are transported to the serial batching machine, and two vehicles are available at time 0, the machine can first process these jobs. Due to $c=h$, the J''-jobs are processed as the first batch at time 0, and the completion time $C(1)$ of this batch is equal to $S_1+s+\sum_{j\in J''}p_j=0+a+h\frac{a}{h}=2a$. Next, vehicle 1 transports the jobs of G_1 one by one, and vehicle 2 transports the jobs of G_2. Let T_i denotes the total running time of vehicle i, for $i=1,2$, we can see that $T_1=\sum_{j\in G_1}t_{J_j'}=2a,T_2=\sum_{j\in G_2}t_{J_j'}=2a$. The J'-jobs are processed as the second batch at time $2a$, and the completion time $C(2)$ of this batch is equal to $S_2+s+\sum_{j\in J'}p_j=2a+a+h\frac{a}{h}=4a$. It is easy to check that $C_{\max}+\alpha(b)\le y$. (See Figure 1)

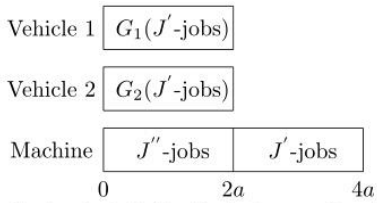

Figure 1. A schedule for the instance of problem TSBSM

If there exists a schedule π with $C_{\max}+\alpha(b)\le y$ to the instance of TSBSM, we show that the 2-Partition problem has a solution.

First, the following properties hold in schedule π:

(i) Schedule π exactly contains two batches, i.e., each batch contains exactly h jobs.

(ii) All J''-jobs are processed as the first batch at time 0.

(iii) All J'-jobs are processed as the second batch at time $2a$.

Next, we prove three properties as follows:

(i) Suppose that there are b batches in schedule π. Due to $c=h,\alpha(b)=3ba$, we have $2\le b\le 3$. If $b=3$, the sum of the makespan and the processing cost

$C_{\max}+\alpha(b)$ is more than $s+\sum_{j\in J''\cup J'}p_j+9a=12a$, which is a contradiction.

Hence, schedule π exactly contains two batches and each batch contains h jobs.

(ii) Denote S_1 and S_2 as the starting time of the first batch and the second batch on the serial batching machine, respectively. Note that $S_1+s+h\frac{a}{h}=S_1+2a\le S_2$. Since the processing time of each batch on the machine is $2a$, we have $C_{\max}+\alpha(b)=S_2+2a+6a\le 10a$. Hence, we obtain that $S_1=0$ and $S_2=2a$. At time 0, there are only J''-jobs available. Thus, all J''-jobs are processed as the first batch at time 0.

(iii) From (i) and (ii), we know that all J'-jobs are processed as the second batch at time $2a$.

Let G_1 and G_2 be a partition of J'-jobs. We assume that vehicle 1 transports the jobs of G_1 one by one, and vehicle 2 transports the jobs of G_2 one by one. Let T_i denotes the total running time of vehicle i, for $i=1,2$. Based on the above discussion, the starting time of the second batch satisfies $S_2=2a\ge\max\{T_1,T_2,2a\}$, where $T_1=\sum_{j\in G_1}2a_j\le 2a, T_2=\sum_{j\in G_2}2a_j\le 2a$. Due to $T_1+T_2=\sum_{j\in H}2a_j=4a$, we have $\sum_{j\in G_1}a_j=\sum_{j\in G_2}a_j=a$. Then it is easy to see that G_1 and G_2 form a solution to the 2-Partition problem instance. Theorem 2 follows.

4.2 APPROXIMATION ALGORITHM

The proof of theorem 2 indicates the problem $D\to 1\,|\,m\ge 1,c\ge 1,s-batch,p_j=p\,|\,C_{\max}+\alpha(b)$ is NP-hard even if $t=0$. When the returning time of vehicle is 0, we present the following approximation algorithm and analysis its worst case ratio.

TSPT-DP Algorithm

Step 1: In the transportation part, assign jobs to vehicles by the SPT rule of the transportation times, i.e., always assign the shortest transportation time job to the available vehicle ;

Step 2: Renumber the jobs in the non-decreasing arrival time order, i.e., $r_1\le r_2\le\cdots\le r_n$;

Step 3: In the processing part, use the dynamic programming algorithm *DP* for batching and processing jobs.

Let π be the solution generated by the TSPT-DP algorithm for the problem $D\to 1\,|\,m\ge 1,t=0,c\ge 1,$ $s-batch,p_j=p\,|\,C_{\max}+\alpha(b)$. We denote by π' the solution generated by assigning jobs to vehicles by the SPT rule of the transportation times, and processing the same number of jobs in each batch coincide with that of the optimal solution π^* as early as possible (maybe wait).

Therefore, π' transports jobs the same as π and uses the same batching policy as π^*. Consequently, we have $r_j^{\pi'}=r_j^{\pi}, j=1,2,\ldots,n$, and $n_i^{\pi'}=n_i^*, 1\le i\le b^*=b^{\pi'}$, $\alpha(b^*)=\alpha(b^{\pi'})$. By Theorem 1,

$$C_{\max}^{\pi}+\alpha(b^{\pi})\le C_{\max}^{\pi'}+\alpha(b^{\pi'}). \tag{2}$$

Lemma 2. $r_j^{\pi'}\le(2-\frac{1}{m})r_{[j]}^*, 1\le j\le n$.

Proof. Since $r_{[j]}^*$ is the arrival time of the j-th arrived job in π^*, it follows $r_{[1]}^*\le r_{[2]}^*\le\cdots\le r_{[n]}^*$, and $t_1,t_2,\ldots,t_j$ are the j minimum transportation times. Thus, we have

$$r_{[j]}^*\ge\max\{t_{[1]},t_{[2]},\cdots,t_{[j]},\frac{1}{m}\sum_{l=1}^{j}t_{[l]}\}\ge\max\{t_j,\frac{1}{m}\sum_{l=1}^{j}t_l\}. \tag{3}$$

On the other hand, as π' uses the SPT rule of the transportation times to assigning jobs to the vehicles,

$$r_j^{\pi'}\le(1-\frac{1}{m})t_j+\frac{1}{m}\sum_{l=1}^{j}t_l\le(2-\frac{1}{m})r_{[j]}^*, 1\le j\le n. \tag{4}$$

Lemma 3. $C^{\pi'}(b^{\pi'})\le(2-\frac{1}{m})C^*(b^*)$.

Proof. Since π' and π^* have the same number of jobs in each batch, we denote $n_i^{\pi'}=n_i^*=n_i$, $|B_i^{\pi'}|=|B_i^*|=|B_i|=n_i-n_{i-1}, 1\le i\le b^*=b^{\pi'}$. $r_{n_i}^{\pi'}$ and $r_{[n_i]}^*$ are denoted as the arrival time of the last arrived job $J_{n_i}^{\pi'}$ and $J_{[n_i]}^*$ in the i-th batch in π' and π^*, respectively.

By Lemma 2 and (4), we have

$$\begin{aligned}C^{\pi'}(1)&=r_{n_1}^{\pi'}+s+|B_1|\,p\le(2-\frac{1}{m})r_{[n_1]}^*+s+|B_1|\,p\\&\le(2-\frac{1}{m})(r_{[n_1]}^*+s+|B_1|\,p)=(2-\frac{1}{m})C^*(1).\end{aligned} \tag{5}$$

By Lemma 1(iii) and (5),

$$\begin{aligned}C^{\pi'}(2)&=\max\{r_{n_2}^{\pi'},C^{\pi'}(1)\}+s+|B_2|\,p\\&\le(2-\frac{1}{m})\max\{r_{[n_2]}^*,C^*(1)\}+s+|B_2|\,p\\&\le(2-\frac{1}{m})(\max\{r_{[n_2]}^*,C^*(1)\}+s+|B_2|\,p)\\&=(2-\frac{1}{m})C^*(2).\end{aligned} \tag{6}$$

Repeat the above process, we get the result

$$\begin{aligned}C^{\pi'}(b^{\pi'})&=\max\{r_{n_{b^{\pi'}}}^{\pi'},C^{\pi'}(b^{\pi'}-1)\}+s+|B_{b^{\pi'}}|\,p\\&\le(2-\frac{1}{m})\max\{r_{[n_{b^*}]}^*,C^*(b^*-1)\}+s+|B_{b^*}|\,p\end{aligned}$$

$$\le (2-\frac{1}{m})C^*(b^*).$$

Theorem 3. For the problem $D \to 1 \mid m \ge 1, t = 0, c \ge 1, \quad s-batch, p_j = p \mid C_{\max} + \alpha(b)$, the worst case ratio of TSPT-DP algorithm is not greater than $2-\frac{1}{m}$, and the bound is tight.

Proof. By (2) and Lemma 3, we have

$$\begin{aligned} C^{\pi}_{\max} + \alpha(b^{\pi}) &\le C^{\pi'}_{\max} + \alpha(b^{\pi'}) = C^{\pi'}(b^{\pi'}) + \alpha(b^{\pi'}) \\ &\le (2-\frac{1}{m})C^*(b^*) + \alpha(b^*) \\ &\le (2-\frac{1}{m})(C^*_{\max} + \alpha(b^*)). \end{aligned} \tag{7}$$

We can conclude that the worst case ratio of TSPT-DP algorithm is at most $2-\frac{1}{m}$. To show the tightness, let us consider the following instance: $n = m^2 - m + 1$, $t = 0$, $t_1 = t_2 = \cdots = t_{m^2-m} = 1, t_{m^2-m+1} = m$, $s = p = 0$, $c = 1$, and $\alpha(b) = 0$. Clearly, both TSPT-DP and the optimal algorithm must process jobs in $m^2 - m + 1$ batches. Consequently, we have $C^{\pi}_{\max} = 2m - 1$, $C^*_{\max} = m$, and $\alpha(b^{\pi}) = 0$, $\alpha(b^*) = 0$. Thus, the desired result follows.

5 Conclusion

In this paper, we studied the problem of coordinated scheduling on a serial batching machine with transportation. Under the condition of the job processing times are equal, if the job assignment to the vehicles is predetermined, we provide a polynomial time dynamic programming algorithm, for the general problem, we prove it is NP-hard. When the returning time of vehicle is 0, we present the approximation algorithm TSPT-DP and prove that the worst case ratio of the algorithm is not greater than $2-\frac{1}{m}$, and the bound is tight.

Several possible extension to this research can be considered, such as, minimizing maximum job tardiness, developing effective heuristics to solve the general problem, et al.

Abstract

This paper presents a new chaos control method to control the unified chaotic system to zero. In order to control a unified chaotic system to zero, the first step is to design a stable system, which stable to zero base on tridiagonal matrix stability theory, the stable system as the master system. The second step is to make the unified chaotic system with controlled as slave system, the third step to make the master system and the slave system synchronization. Different system state apply different adaptive synchronize method to realize synchronization. The adaptive control law and parameter update law are obtained base on Lyapunov stability theory. Numerical simulations are presented to demonstrate the effectiveness of theoretical analysis.

Keywords: chaos control, adaptive hybrid synchronization, tridiagonal structure matrix stability theory

1 Introduction

In 1990, Ott, Grebogi and Yorke presented the OGY method on chaos control [1]. After their pioneering work, chaos control has gained more interest in nonlinear problems and there have been a lot of progress in this field [2-5]. Generally, there are two control ways: feedback control and nonfeedback control. Feedback methods [6-10] are used to stabilize the unstable periodic orbit of chaotic systems by feedback their states. Nonfeedback methods [11, 12] are adopted to suppress chaotic behaviour by apply periodic perturbations to some parameters or variables. With the development of chaos control technology, all kinds of methods are developed.

This paper proposes a new chaos control method to control the unified chaotic system to zero, the new method base on tridiagonal structure matrix stability and hybrid synchronization.

This paper is organized as follows. In the next section, we analyse the tridiagonal structure matrix stability theory and system with tridiagonal structure matrix. In section 3, we introduce the hybrid synchronization theory. In section 4, we make use of tridiagonal matrix stability theory and adaptive hybrid synchronization to control the unified chaotic system to zero. In section 5, some numerical simulations are done to test the effectiveness of theoretical analysis. Finally, some conclusions are drawn in section 6.

2 The theory

2.1 THE TRIDIAGONAL STRUCTURE MATRIX STABILITY THEORY

Lemma 1 [13, 14] If the nonlinear system has the following forms of tridiagonal structure:

$$\dot{X} = \begin{bmatrix} -k_1 & f_1(x) & & \\ -f_1(x) & -k_2 & \ddots & \\ & \ddots & \ddots & f_{n-1}(x) \\ & & -f_{n-1}(x) & -k_n \end{bmatrix} X \text{ , where}$$

$X(t) = (x_1, x_2, \cdots, x_n)^T \in R^n$ is state vectors, $f_j(x_i)(j = 1, 2, \ldots, n-1, i = 1, 2, 3, \ldots, n)$ are function about x_i , $k_i \in R^+(i = 1, 2, \ldots, n)$, the state vectors x of nonlinear system will be globally asymptotically stabilized to origin.

Proof: A positive definite function is as follows, $V = \frac{1}{2} X^T X$.

The derivative of V , $\dot{V} = -\sum_{i=1}^{n} K_i x_i^2 < 0$.

Due to V is the Lyapunov function and x will be globally asymptotically stabilized to origin [14].

2.2 SYSTEM WITH TRIDIAGONAL STRUCTURE MATRIX

Due to permanent magnet synchronous motor (PMSM) system has tridiagonal structure, we introduce PMSM system.

* ***Corresponding author*** e-mail hyl200199@163.com

Model of PMSM can be expressed as follows [15],

$$\begin{bmatrix}\dot{x}_1\\ \dot{x}_2\\ \dot{x}_3\end{bmatrix}=\begin{bmatrix}-1 & x_3 & 0\\ -x_3 & -1 & \gamma\\ 0 & \sigma & -\sigma\end{bmatrix}\begin{bmatrix}x_1\\ x_2\\ x_3\end{bmatrix}. \quad (1)$$

The parameters γ and σ ($\sigma>0$) can decide the system (1) is chaos or not [16]. Fig. 1 show the chaotic character of system (1) with $\gamma=20$ and $\sigma=3$, initial values $x_1(0)=0.1, x_2(0)=0.2, x_3(0)=0.4$. From Figuge 1 it can be concluded that system (1) is in chaotic state.

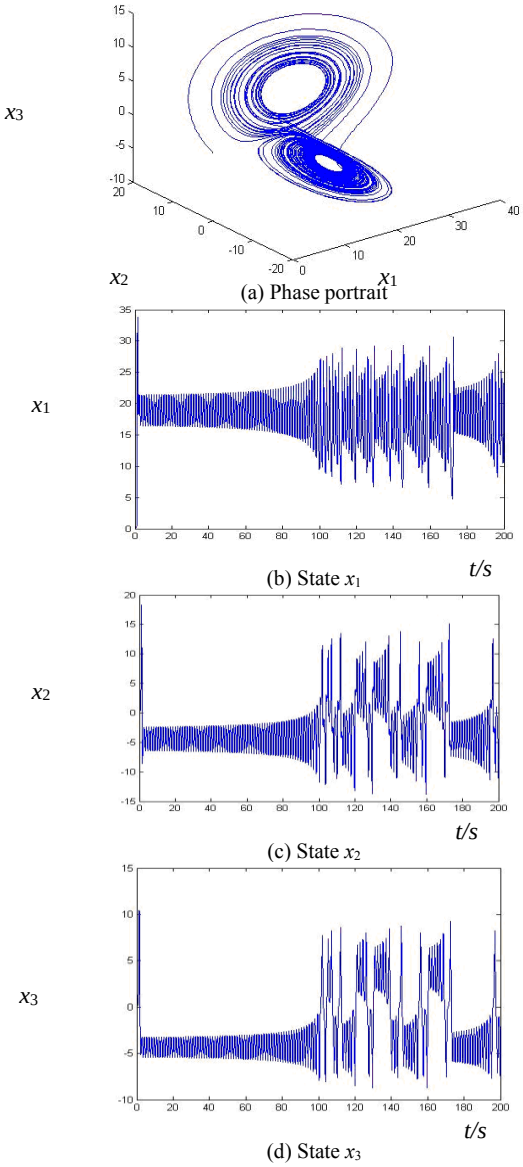

FIGURE 1 the chaotic character of system (1) when $\gamma=20$ and $\sigma=3$

System (1) has tridiagonal structure matrix form when parameters $\gamma=$-σ, which can be expressed as follows,

$$\begin{bmatrix}\dot{x}_1\\ \dot{x}_2\\ \dot{x}_3\end{bmatrix}=\begin{bmatrix}-1 & x_3 & 0\\ -x_3 & -1 & -\sigma\\ 0 & \sigma & -\sigma\end{bmatrix}\begin{bmatrix}x_1\\ x_2\\ x_3\end{bmatrix}. \quad (2)$$

Figure 2 shows states changes of system (2) when parameters $\sigma=5$, initial values $x_1(0)=0.1, x_2(0)=0.2, x_3(0)=0.4$. From Figure 2, it can be concluded that system (2) is stabilized to zero.

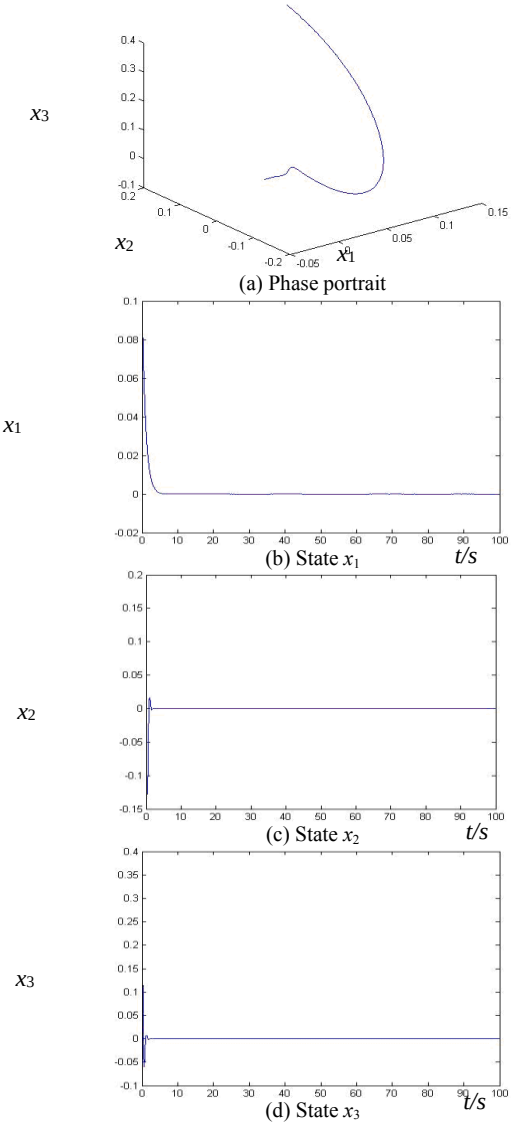

FIGURE 2 Trajectories of the system (2) states when $\sigma=5$

3 Hybrid Synchronization

Consider the following three-dimensional master system (3) and slave system (4),

$$\dot{x}=f(t,x), \quad (3)$$

$$\dot{y}=g(t,y)+u(t,x,y), \quad (4)$$

where $x(t)=(x_1,x_2,x_3)^T\in R^3$ and $y(t)=(y_1,y_2,y_3)^T\in R^3$ are master and slave state vectors respectively, $f:R^3\to R^3$ and $g:R^3\to R^3$ are continuous nonlinear vector functions and $u(t,x,y)=(u_1,u_2,u_3)^T\in R^3$ is control input for synchronization between master system (3) and slave system (4).

Definition 1. It is said that hybrid synchronization occurs between master system (3) and slave system (4) if satisfy the following conditions:

Define $s(r)$ is a function, where r is state vector. Satisfy

$$\lim_{t\to\infty}\|e_1(t)=y_1(t)-s(x_1(t))\|=0.$$

Define λ is constant and satisfy

$$\lim_{t\to\infty}\|e_2(t)=y_2(t)-\lambda x_2(t)\|=0.$$

Define $m(t)$ is a function and satisfy

$$\lim_{t\to\infty}\|e_3(t)=y_3(t)-m(t)x_3(t)\|=0.$$

4 Method

The unified chaotic system [17] is expressed as follows,

$$\begin{aligned}\dot{x}_1&=(25\theta+10)(x_2-x_1)\\ \dot{x}_2&=(28-35\theta)x_1+(29\theta-1)x_2-x_1x_3\\ \dot{x}_3&=x_1x_2-\frac{8+\theta}{3}x_3\end{aligned}\quad(5)$$

where $\theta\in[0,1]$. System (5) is chaotic for $\theta\in[0,1]$.

When $\theta\in[0,0.8)$, system (5) reduces to the general Lorenz system; when $\theta=0.8$, it becomes the general Lü system; and $\theta\in(0.8,1]$, system (5) is the general Chen system.

We assume that the system (2) with $\sigma=5$ as master system, system (5) with controlled as the slave system (6) given by,

$$\begin{aligned}\dot{y}_1&=(25\theta+10)(y_2-y_1)+u_1\\ \dot{y}_2&=(28-35\theta)y_1+(29\theta-1)y_2-y_1y_3+u_2\\ \dot{y}_3&=y_1y_2-\frac{8+\theta}{3}y_3+u_3\end{aligned}\quad(6)$$

where u_1,u_2,u_3 are the control input.

By the definition of hybrid synchronization, the error is given by

$$\begin{aligned}e_1&=y_1-s_1(x_1)\\ e_2&=y_2-\lambda x_2\\ e_3&=y_3-m(t)x_3\end{aligned}\quad(7)$$

The error dynamics system is then given as

$$\begin{aligned}\dot{e}_1&=\dot{y}_1-\dot{s}_1(x_1)\dot{x}_1\\ \dot{e}_2&=\dot{y}_2-\lambda\dot{x}_2\\ \dot{e}_3&=\dot{y}_3-\dot{m}(t)x_3-m(t)\dot{x}_3\end{aligned}\quad(8)$$

By substituting Eqs. (2) And (6) in the above equation, we obtain

$$\begin{aligned}\dot{e}_1&=(25\theta+10)(y_2-y_1)-\dot{s}_1(x_1)(-x_1+x_3x_2)+u_1\\ \dot{e}_2&=(28-35\theta)y_1+(29\theta-1)y_2-y_1y_3-\lambda(-x_2-x_3x_1-5x_3)+u_2\\ \dot{e}_3&=y_1y_2-\frac{8+\theta}{3}y_3-\dot{m}(t)x_3-m(t)[5(x_2-x_3)]+u_3\end{aligned}\quad(9)$$

Here, our goal is to achieve hybrid synchronization between two systems with different initial conditions. For this end, the following control laws are designed:

$$\begin{aligned}u_1&=-(25\hat{\theta}+10)(y_2-y_1)+\dot{s}_1(x_1)(-x_1+x_2x_3)-k_1e_1\\ u_2&=-(28-35\hat{\theta})y_1-(29\hat{\theta}-1)y_2+y_1y_3+\lambda(-x_2-x_3x_1-5x_3)-k_2e_2\\ u_3&=-y_1y_2+\frac{8+\hat{\theta}}{3}y_3+\dot{m}(t)x_3+5m(t)(x_2-x_3)-k_3e_3\end{aligned}\quad(10)$$

where $\tilde{\theta}=\theta-\hat{\theta}$, we define $\hat{\theta}$ as estimate of θ of system (6), $\tilde{\theta}$ is estimate error, $k_i>0(i=1,2,3)$.

Substituting Eqs. (10) In Eqs. (9), we obtain

$$\begin{aligned}\dot{e}_1&=25\tilde{\theta}(y_2-y_1)-k_1e_1\\ \dot{e}_2&=-35\tilde{\theta}y_1+29\tilde{\theta}y_2-k_2e_2\\ \dot{e}_3&=-\frac{\tilde{\theta}}{3}y_3-k_3e_3\end{aligned}\quad(11)$$

The parameter update rule for $\hat{\theta}$ is chosen as follows

$$\dot{\hat{\theta}}=\frac{1}{3}e_3y_3-25e_1(y_2-y_1)+e_2(35y_1-29y_2).\quad(12)$$

Theorem 1. The system (6) can be stabilized to zero by hybrid synchronization between master system (2) and slave system (6) when choose the control laws (10) and parameter update rule (12).

Proof. Choose the following Lyapunov function

$$V=\frac{1}{2}(e_1^2+e_2^2+e_3^2+\tilde{\theta}^2),\quad(13)$$

where $\tilde{\theta}=\theta-\hat{\theta}$, the time derivative of Eq. (13) along the trajectory of error system is

$$\dot{V}=\dot{e}_1e_1+\dot{e}_2e_2+\dot{e}_3e_3+\tilde{\theta}\dot{\hat{\theta}},\quad(14)$$

and substitute Eqs. (11) and Eq. (12) in Eq. (14), $\dot{V} = -k_1 e_1^2 - k_2 e_2^2 - k_3 e_3^2$.

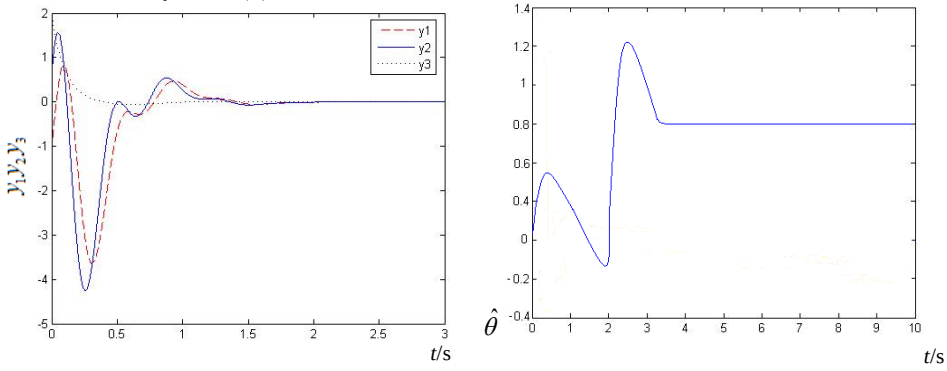
Since $\dot{V} < 0$, the master system (2) and the slave system (6) achieve synchronization. The slave system (6) can be stabilized to zero.

5 Numerical simulations

Numerical simulations are presented to demonstrate the effectiveness of the proposed synchronization controller. Fourth-order Runge-Kutta method is used to solve master system (2) and slave system (6) with time step size 0.0001, the parameter of master system (2) are chosen to be $\sigma = 5$ so that the master system (2) exhibits stable behaviour. The initial conditions of the master system (2) as follows, $x_1(0) = 0.1, x_2(0) = 0.2, x_3(0) = 0.3$, and those of the slave system (6) are $y_1(0) = -1, y_2(0) = 0.6, y_3(0) = 2$.

The estimate parameter of slave system (6) is chosen as $\hat{\theta} = 0.1$ real parameter is $\theta = 0.8$. Moreover, $s_1(r) = \sin r, s_1(x_1) = \sin x_1$, $m(t) = \sin t + 1$, $\lambda = 30$. The control gains are chosen as $k_1 = 0.05$, $k_2 = k_3 = 10$.

The simulations results are illustrated in Fig. 3. From Fig. 3 (a) it can be concluded that system (6) can be stabilized to zero. From Fig. 3 (b) it can be concluded that and estimate parameter value research 0.8.



(a) Trajectories of the states y_1, y_2, y_3 **(b) Parameter identification**

FIGURE 3 System (6) control process

6 Conclusions

In this paper, we propose a chaos control method to control the unified chaotic system with uncertain parameter to zero. The first step is to design a stable system, which stabilizes to zero bases on tridiagonal matrix stability theory, the stable system as master system. The second step is to make the unified chaotic system with controlled as the slave system. The third step is to make the slave system and the master system synchronize. The variables of system apply adaptive function synchronization, adaptive projective synchronization and the adaptive generalized projective synchronization to realize the synchronization of master system and the slave system. Thus, the slave system can be stabilized to zero.

The impact on collaborate level of cluster

Lirong Qiu*

School of Information Engineering, Minzu University of China, Beijing, China

Received 1 March 2014, www.cmnt.lv

Abstract

Due to the impact of the characters of nodes in complex network on collaboration level, we put forward a new iterated game model based on conformist mechanism. In this model, nodes can update tactic not only according to their payoffs but also to their species, which they belong to. The new model can assure that nodes in the same species adopt the same tactic. Simulation results show that the collaboration level of the networks that adopt conformist mechanism is higher than the networks that adopt normal mechanism. In the other words, the collaboration level is in inverse proportion to the species number. On the other hand, we find that the average payoffs increased with the penalty gene instead of increasing alternately. So the new model can promote the collaboration level and the average payoffs of the nodes in network at the same time.

Keywords: Conformist Mechanism, Iterated Game, Collaborate Level, Complex Network

1 Introduction

Traditional evolutionary game theory considers the main nature, which prefers to select selfish and stronger individuals. However, there are lots of cooperation behaviours in nature, which contradicts the natural section rule. Game theory is an efficient tool in the field of studying biological, economic, and social relations of complex network etc. Especially after the notion of Prisoner's Dilemma Game (PD game) proposed by Neumann and Morgenstern, various related research works are applied into many fields. The prisoner's dilemma is a canonical example of a game analysed in game theory that shows why two purely "rational" individuals might not cooperate, even if it appears that it is in their best interests to do so. It was originally framed by Merrill Flood and Melvin Dresher working at RAND in 1950. Albert W. Tucker formalized the game with prison sentence rewards and named it "prisoner's dilemma" (Poundstone, 1992).

The basic idea of PD game is as follows: two thieves are arrested and imprisoned. Each thief is in solitary confinement with no means of speaking or exchanging messages with the other. Here is how it goes:

(1) If A and B both defect from the other, each of them serves 2 years in prison.

(2) If A defects from B but B remains silent, A will be set free and B will serve 3 years in prison (and vice versa).

(3) If A and B both remain silence (which means that they cooperate), both of them will only serve 1 year in prison (on the lesser charge).

It is implied that the prisoners will have no opportunity to reward or punish their partner other than the prison sentences they get, and that their decision will not affect their reputation in future. Because defect from a partner offers a greater reward than cooperating with them, all purely rational self-interested prisoners would defect from the other, and so the only possible outcome for two purely rational prisoners is for them to defect from each other. The interesting part of this result is that pursuing individual reward logically leads both of the prisoners to betray, when they would get a better reward if they both cooperated. In reality, humans show a systematic bias towards cooperative behaviour in the similar games, much more than predicted by simple models of "rational" self-interested action. A model based on a different kind of rationality, where people forecast how the game would be played if they formed coalitions and they maximize their forecasts, has shown to make better predictions of the rate of cooperation in this and similar games given the payoffs of the game.

Generally, in PD game, each party (denoted as P1 and P2) has two choices: Cooperation (C for short) and Defection (D for short). Utility is defined as follows:

The utility is T for P1 when P1 adopts D and P2 adopts C;

The utility is S for P1 when P1 adopts C and P2 adopts D;

Both P1 and P2 get R if they adopt C;

Both P1 and P2 get P if they adopt D.

We often use a matrix A to describe the relationships between P1 and P2.

$$A=\begin{bmatrix} R & S \\ T & P \end{bmatrix},\ T>R>P>S,\ 2R>T+S.$$

For one-short PD game, where the game is played only once, both parties would rather to adopt D since D is dominating strategy for them. However, the optimal result for both parties is (C, C) since R is bigger than P.

* ***Corresponding author*** e-mail: qiu_lirong@126.com

Therefore, the problem is how to encourage both parties to cooperation in PD game. One solution for this problem is iterated PD game, where parties interact for several rounds. The reason is that in iterated PD game, parties can adopt certain retaliatory measures to punish those who adopt D. Thus, parties who adopt D may not defect in the following rounds PD games. Therefore, both parties would like to cooperate in iterated PD games.

On the other hands, cooperation often appears in complex network. Santosand Pacheco [1] fink that the scale-free network is beneficial to cooperation emergence and maintenance. Furthermore, they also discuss snow-drift game model in scale-free network [2] and the results show that mixed network is more conductive of cooperation emergence. Vainstein and Arenzon [3] find that some potential disruption in sparse grid can strengthen the density of cooperation. Riolo [4] studied a game model, where does not exists any reciprocity.

In this model, parties decide whether to cooperate according to the similarity of their opponents. Although this model may boost cooperation, it has a strong assumption. That is each party in this game must interact with those who are similar to him. This game is degenerated to PD game once this assumption is released. Therefore, cooperation may not appear in the model without reciprocity mechanism.

This paper proposes a conformity mechanism, which considers the impact of conformity to the results of game theory. Here parties should not only consider his own utility but also majority parties in the same set. Firstly, this paper describes the basic idea of conformity scheme. Secondly, discuss the simulation results of the scheme. The results show that this scheme can greatly boost cooperation among parties in network. Furthermore, conformity can avoid the average utility rise alternately such that it has a proportional relationship with punishment factor.

2 The conformity scheme

In order to boost cooperation among parties, scientists propose various methods and schemes. A simplest strategy is Tit-for-Tat (TFT for short).

Tit for tat is a highly effective strategy in game theory for the iterated PD game. The strategy was first introduced by Anatol Rapoportin Robert Axelrod's two tournaments [1], held around 1980. Notably, it was (on both occasions) not only the simplest strategy but also the most successful in direct competition. An agent using this strategy will first cooperate, and then subsequently replicate an opponent's previous action. If the opponent previously was cooperative, the agent is cooperative. If not, the agent is not. This is similar to super-rationality and reciprocal altruism in biology. The success of the tit-for-tat strategy is astonishing, which is largely cooperative despite that its name emphasizes an adversarial nature. Arrayed against strategies are produced by various teams it won in two competitions. After the first competition, new strategies formulated specifically to combat tit-for-tat failed due to their negative interactions with each other; a successful strategy other than tit-for-tat would have had to be formulated with both tit-for-tat and itself in mind.

The results may give insight into how groups of animals (and particularly human societies) live in largely (or entirely) cooperative societies, rather than the individual way, which is in "red in tooth and claw" way that might be expected from individuals engaged in a Hobbesian state of nature. This, and particularly its application to human society and politics, is the subject of Robert Axelrod's book “The Evolution of Cooperation”.

Moreover, the tit-for-tat strategy has been of beneficial used to social psychologists and sociologists in studying effective techniques to reduce conflict. Research has indicated when individuals who have been in competition for a period of time no longer trust one another, the most effective competition reverser is the use of the tit-for-tat strategy. Individuals commonly engaged in behavioural assimilation, a process in which they tend to match their own behaviours to those displayed by cooperating or competing group members. Therefore, if the tit-for-tat strategy begins with cooperation, then cooperation ensues. On the other hand, if the other party competes, then the tit-for-tat strategy will lead the alternate party to compete as well. Ultimately, each action by the other member is countered with a matching response, competition with competition and cooperation with cooperation.

In the case of conflict resolution, the tit-for-tat strategy is effective for several reasons: the technique is recognized as clear, nice, provocable, and forgiving. Firstly, it is a clear and recognizable strategy. Those using it quickly recognize its contingencies and adjust their behaviour accordingly. Moreover, it is considered to be nice as it begins with cooperation and only defects in following competitive move. The strategy is also provocable because it provides immediate retaliation for those who compete. Finally, it is forgiving as it immediately produces cooperation should the competitor make a cooperative move.

Individuals who employ the tit-for-tat strategy are generally considered to be tough but fair—a disposition that is often respected in the business/organization world. Those who always cooperate with a competitor are often viewed as weak, while those who consistently compete are perceived as unfair. In any case, the implications of the tit-for-tat strategy have been of relevance to conflict research, resolution and many aspects of applied social science.

In addition, if parties in game theory can observe other parties’ strategy and assign values on reputation, then this indirect reciprocity can explain why cooperation emergence. However, it is a controversial topic which scheme leads to this cooperation. Recently, some research works show that some different indirect reciprocity can effectively result in cooperation emergency.

The models without reciprocity can also lead to cooperation emergence such as Riolo model. Although this model has some shortcomings it has caught wide interests since it makes parties to cooperate on the basis of similarity. If interaction is not random, then the group of co-operators can exist in the settings without cheaters. That is cooperation mechanism based on similarity can lead to a high level of cooperation.

Previous models only consider his own utility while they do not consider the impact when other parties update their strategy. In fact, parties' strategy are easy affected by other parties' strategy. This is what we called conformity. More specifically, parties would like to adopt the strategies which are adopted by most parties in network although this strategy may be not optimal.

In interpersonal network, nodes denote parties in games, lines between nodes denote the relationships of two parties. Previous research work often neglects some properties of nodes. In this paper, we set up a network considering those properties. For example, a node has commercial benefits and then we can divide nodes into several groups according to their different characters. The conformity idea is similar to Riolo model. The difference lies in that Riolo model release the limits for parties, where they cannot only interact with parties in the same group but also parties in other groups. Furthermore, the utility matrix is changed with strategy. In iterated PD games, we adopt dynamic matrix. The game model is set up as follows.

(1) Choose Zachary [6] network as research object. Zachary's karate club: social network of friendships between 34 members of a karate club at a US university in the 1970s. Please cite W. W. Zachary, An information flow model for conflict and fission in small groups, Journal of Anthropological Research 33, 452-473 (1977).

(2) Set up utility matrix. We adopt the matrix as Nowak and May A=$\begin{bmatrix} 1 & 0 \\ b & 0 \end{bmatrix}$, where 1<b<2.

(3) Randomly initialize strategies for each party.

(4) Node I play games with his neighbour j. If i adopt strategy C then we do not update utility matrix.

Otherwise, the game proceed into next round. Before entering the next round, let b=b-Q, where Q is punish factor. The utility of each neighbour lj_i of party i is $S(lj_i)$. After party i interact with all neighbours, choose maximize utility $\max(S(lj_i))$ among $lj_{\max i}$. Finally update the strategy of party i as his neighbours' strategy $lj_{\max i}$.

(5) Entering the next round, divide different groups according to their strategies. That is, parties belong to the same group if they adopt same strategies. Here in order to contrast the efficiency of new schemes, we adopt a reference experiment. In the reference experiment nodes adopts the strategy of those who have highest utility.

(6) Repeat step (4), (5) till the game end.

In the new model, nodes in network first play game with his neighbours and adopt strategies of those who have the highest one. If the game proceeds into the next round, nodes will adopt the strategy, which is adopted by most parties in the same group. This agrees with conformity and is presented in Figure 1.

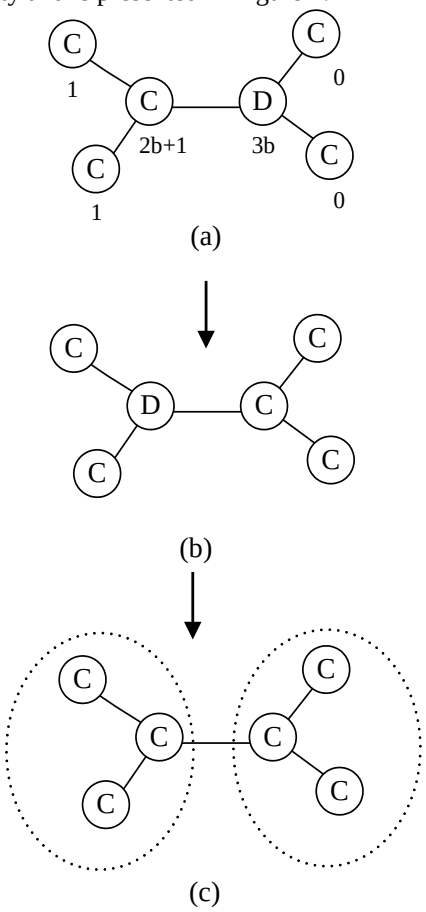

FIGURE 1 The proceed of conformity

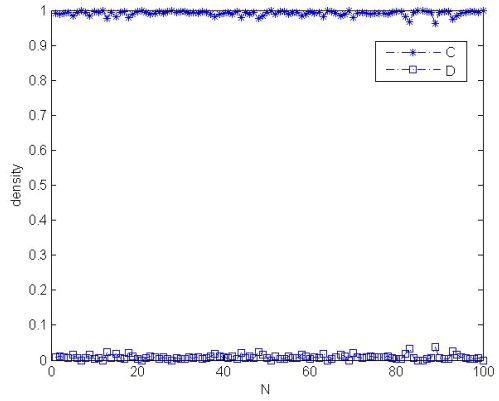
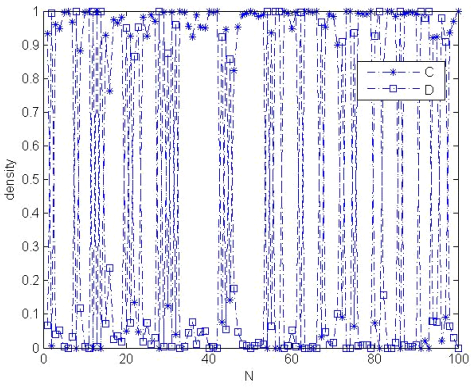
Since initial strategy is randomly set, the initial utility of the node is shown in Figure 1(a). Then after one round of game, node A adopt the strategy of node B. Since node B has the highest utility among all neighbours of node A, node A adopt the strategy of node B in next round. For the same reason, node B adopts the strategy of node A. This proceed is shown in 1(b). However, node A should adopt the strategy of those most parties adopt in the same group according to the conformity scheme as shown in 1(c), where dotted line mean two groups. We can see that the cooperation level in the network is improved due to conformity.

3 Simulation results

When node is in the same group, this model reduces to the model in [4]. When parties update their utility after one round, then this model reduce to the model in [7]. When the network is divided into three groups, the impact of this model and models in [7] is shown in Figure 2.



(a)

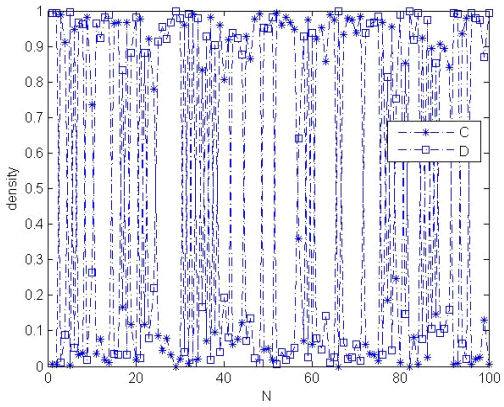


(b)

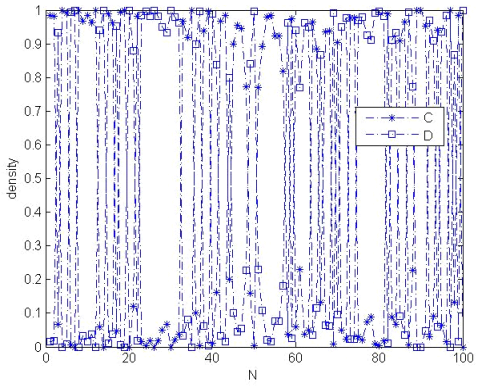
FIGURE 2 Network strategy density (when there are 3 groups)

Figure 2(a) denotes the network strategy density when the network is divided into 3 groups and the rounds number is 100. Figure 2(b) denotes that each node update their utility according to his own strategy. As shown in Figure 2, the cooperation and defect strategy rise alternatively in Tomochi and Kono and there are no obvious bounds. And cooperation level is obviously higher than defect level in our model. This illustrate that conformity greatly improve the cooperation level in the network. Iterated games can improve cooperation level. Therefore, most parties in the network are like to adopt cooperation. Furthermore, nodes in the whole group choose their strategy according to conformity scheme. So we can regard that individual party may give up his own benefit in order to conform to the benefit of the whole group.

Note that conformity scheme may lose his efficiency when the number of nodes is equal to the whole network. That is, each node belongs to one group. The reason is that each node will only consider the strategy of him. There is no group to conform. In order to study the impact of group scale to cooperation level, we discuss the cooperation and defect density when there are 10 groups in one network. The results are shown in Figure 3. Just as before, we also adopt Tomochi and Kono as a reference.



(a)



(b)

FIGURE 3 Network strategy density (when there are 10 groups)

Compared with 3(a) and Figure 2(a), we find that cooperation and defect rise alternatively in both figures and there are also no obvious bound in these two figures. This results show that the impact of conformity scheme when the group number is large is less obvious than that when the group number is small. Compared 3(a) and Figure 3(b), we find that the former has a higher cooperation levels, which shows that conformity scheme is dominating.

Furthermore, we also find that conformity can also improve the average utility in the whole network. The average utility alternatively increases in [7]. However, when we adopt conformity scheme, there is a linear relation between average utility and punishment factor Q. Figure 4 denotes the average utility when the group number is 3 and 10. The results show that the average utility becomes small when the number of groups becomes larger.

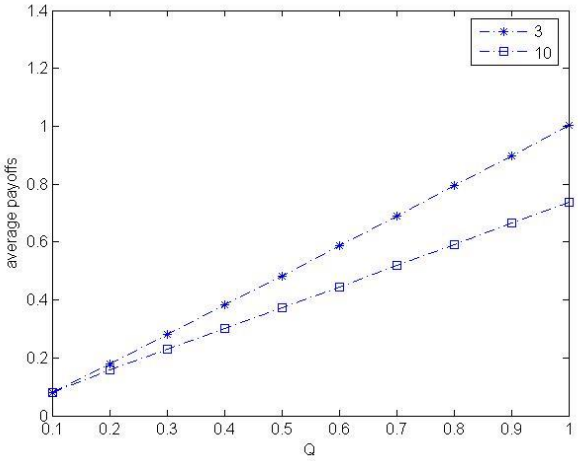


FIGURE 4 Network average utility

4 Conclusions

With the development of complex network, the structure of complex network becomes more and more popular especially for the cooperation strategy. Game theory on complex networks will be more and more interesting and become to be the centre of the evolution theory. The emergence of group cooperative behaviour and stability maintenance are confused phenomenon for scientists and the structure evolution plays an important role in complex system.

This paper proposes a conformity scheme to boost cooperation among parties. The basic idea is to use strategies in iterated games such that each node adopts the strategy of those who have the highest utility in each round. That is, if the strategy conforms to the majority strategies in the group, then parties remain to adopt this strategy. Otherwise, parties adopt the strategy, which is adopted by most nodes in the same group. The simulation results show that this conformity scheme can greatly improve the cooperation level in the network.

Abstract

In order to get a faster, more effective and stable control over lower extremity exoskeleton of power assist robot, precise examination on gait information is necessary, thus it is so important to design and establish a gait recognition system with accurate detection. In this paper, a wireless in-shoe wearable plantar pressure acquisition system based on ATmega16 and 8 FSR sensors will be applied to data acquisition for the gaits which consist of standing, walking, jumping and going upstairs. And four volunteers (2 males and 2 females) will be invited in this research to collect the pressure information. The NNT of MATLAB will be applied to establish an 8-12-4 BP neural net model. The input factors come from the eight sensors of plantar pressure system, the output is gait category. Proved by a great deal of experiments, the gait recognition method proposed in this research is quite feasible.

Keywords: gait recognition, BP neural networks, plantar pressure, lower extremity exoskeleton of power assist robot

1 Introduction

1.1 RESEARCH STATUS AND APPLICATION PROSPECTS OF GAIT RECOGNITION SYSTEM

As a developing research field about the technology in recognition of biological characteristics, gait recognition [1] has become the focus of computer fans. How to obtain effective gait information and the accuracy of gait recognition have become the key points and difficulty in recent study.

Bobick [2] has determined human's characteristics of step and extensibility of legs with the aid of structured analysis method in Georgia Tech. The outcome was concluded by some experiments, which involved the problems of shadow and sunlight, because the experiments were finished indoors and outdoors. Kale [3] used the human's side profiles in binarized images as the features of images. Then for each person, they used c-means algorithm to choose a sample in a single gait cycle. In the process of recognition, the FED vector between each frame in a gait sequence and the sample was calculated and recognized by HMM. Lee [4] used seven ovals to represent different body parts in the binarized images of human's side profile. Using four characteristic values including barycenter to represent the height of the body image's barycentre. Meanwhile all 29 characteristic values were used to represent the image of a person's body side. The gait recognition was completed via the method of template matching. In Little and Boyd's [5] method, the gait recognition was achieved with the help of gait sequence images' optical frequency and phase. While Phillips [6] utilized different time-space domain template to accomplish the gait recognition. For Cunado [7], a pendulum module involved thigh and shank was established so that gait characteristics could be detected from the frequency component of the pendulum angel signal.

Gait recognition is a kind of technology that is used for detecting within a certain distance in detecting human's instinct biological characteristics like fingerprint identification and face recognition, some problems related to close contact in physics always exist. In this way, gait recognition can be applied well and has a bright future.

1.2 THE BASIC PRINCIPLES AND CHARACTERISTICS OF ARTIFICIAL NEURAL NETWORKS

Artificial Neural Networks (ANN), also called Neural Networks(NN), is a kind of artificial bionic model based on the theory which about synaptic connections in the brain. It is made up of a great deal of neurons [8].

Neuron, the most basic unit in the neural network, plays a quite important role in the network. Different networks are made of different neurons which connects with each other in different ways, which means the structures of neural networks are also various. So they have various functions, too.

ANN has the following outstanding characteristics:

1) it can make the input sample approximate complex non-linear function relation well;

2) it has good fault-tolerant ability and robustness;

3) NN uses the paralleled distributed methodology to manipulate the input sample's information, which makes scientists can finish big-scale arithmetical operation faster.

1.3. NEURAL NETWORK MODEL

BP neural network, also called Error Back Propagation Neural Network, is a kind of forward multi-layered neural network. In BP network, signals propagate forwards, while errors propagate backwards. BP network often includes input layer, hidden layer and output layer. Theoretically, it can increase the accuracy and expression ability of the network by adding hidden layers.

According to Kolmogorov Theory, a three-layer BP network can form any mapping from m-dimensions to n-dimensions, which means that just one hidden layer is enough. Such a NN can approximate any continuous function correctly [9] (Figure 1).

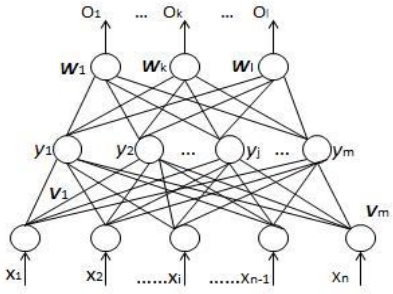

FIGURE 1 A single hidden layer of BP network model

2 BP neural network established for gait recognition

2.1 IN-SHOE WEARABLE PLANTAR PRESSURE ACQUISITION SYSTEM

Due to several outstanding characteristics which include portability, flexibility and great convenience, plantar pressure acquisition system has been one of the most important application techniques in gait recognition and has been extended to other relevant fields, such as medical testing, sport science and robotics research.

In-shoe plantar pressure acquisition system, which is able to measure plantar forces and detect gait-phases of human at the same time, has become an attractive alternative for ground mounted force platform. Researchers in this field can make more products by using it [10].

Many researchers have proposed many different numbers of force sensors to recognize the gait phase. For instance, a research group used four force sensors to identify the gait phases with a classification algorithm and has obtained good results [11], Faivre employed eight sensors in the in-shoe plantar pressure system according to the literature [12], and flexible force sensor(Tekscan Inc., USA) and FSR sensor(Interlink Electronics, USA) has been commonly used.

As we illustrated in the Figure 2, the heel, metatarsals and hallux are the main regions to sustain people's weight [13]. Thus, we designed to place four force sensors configured at the Heel, Meta 2nd, Meta 1st and Hallux for each foot to obtain plantar pressure and detect gait phase. These sensors were packaged in two pairs of insole and the insole was adhered to a pair of shoes, as shown in Figures 3 and 4.

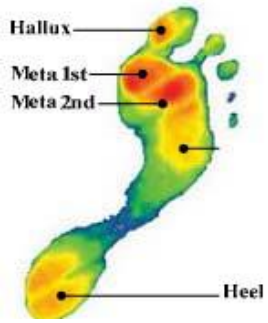

FIGURE 2 Plantar pressure distribution [14]

FIGURE3 The package of sensors in the shoes

FIGURE4 The position of sensors in insole

2.2 DATA ACQUISITION AND PROCESSING

In order to get more universal and accurate data of plantar pressure, we invited four volunteers: two females and two males to conduct the data acquisition of this experiment. The brief information of these four volunteers is shown in Table 1.

TABLE 1 General information of volunteers

Gender	Age	Height	Weight	Feet size
Female	23	167cm	55kg	39cm
Female	22	160cm	48kg	37cm
Male	20	174cm	60ke	41cm
Male	22	167cm	65kg	40cm

A network can have a plurality of output variables, in this study, there are four output variables, because of the input of numeric variables, the output is also corresponding to numerical quantity. Actually, network's output is only 0 to 1 or -1 to 1, so the desired output must

need to be normalized.

Normalization is a method of data processing by means of the network input and output limits in the [0,1] or [-1,1]. Normalization process is performed in order to avoid absolute error components that the large value is large and the small one is small, the network will just adjust the weight value of the total error, as a result, the output component that has a small share of the total error will have larger relative error. In this paper, the output of all the types of gait is normalized, thus [1,0,0,0] was chosen to represent 'standing'; [0,1,0,0] represented 'walking'; [0,0,1,0] for 'jumping' and [0,0,0,1] for 'going upstairs'.

2.3 ESTABLISH GAIT RECOGNITION SYSTEM BASED ON BP NEURAL NETWORK MODEL

The purpose of this research is to achieve information of human gait which gathered based on plantar pressure system and then use MATLAB software to simulate the BP algorithm to find the suitable BP network model to distinguish the type of gait. A total of eight input characteristic value and four output type value. After a large number of experiments, according to preparation of the train-dataset, test-dataset and design of the BP network' structure, the following three-tier network model constructed by MATLAB R2012a's BP neural network toolbox [15], a good gait recognition system was obtained in this research:

1) eight input-layer neurons;

2) output-layer nodes in the hidden layer was set to twelve according to the number of training samples and the dimension of the input and output layer nodes;

3) the dimension of the output layer equals the types of gait, four; the construction principle of the output layer is: different types of output in the corresponding position is 1 and the rest position is 0, for example, [1,0,0,0] represented 'standing', [0,1,0,0] represented 'walking', [0,0,1,1] for 'jumping' and [0,0,0,1] for 'going upstairs'.

4) logsig is selected as the network error transfer function from the input layer to the hidden layer and logsig from hidden layer to the output layer.

5) we chose Powell-Beale connection gradient BP training function 'trainlm' as the learning function;

6) The learning numbers of the network is set to 3000, the learning rate is set to 0.0005 and training objectives set to 0.004. We used an 800x8 dataset which contained 200 data from 'standing', 200 data from 'walking', 200 data from 'jumping' and 200 data from 'going upstairs' to train the network. A 400x8 data that comprised 100 data from 'standing', 100 data from 'walking', 100 data from 'jumping' and 100 data from 'going upstairs', with the accuracy of the test results and the square error value we can judge whether the types of gait can be classified.

3 The training and simulation results of BP neural network model

After the BP neural network's hidden layers, the number of neurons, the input and output layers are all determined, it is virtually certain that the network model can be simulated by programming in MATLAB R2012a(as shown in Figure 5)

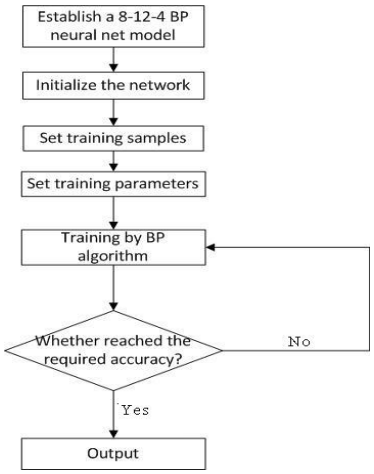

FIGURE 5 System architectures of based on BP Neural Networks of the gait recognition system

The final classification model based on BP neural network was done by the algorithm designed by this research through neural network toolbox of MATLAB. And result of final gait recognition was shown in Figure 6.

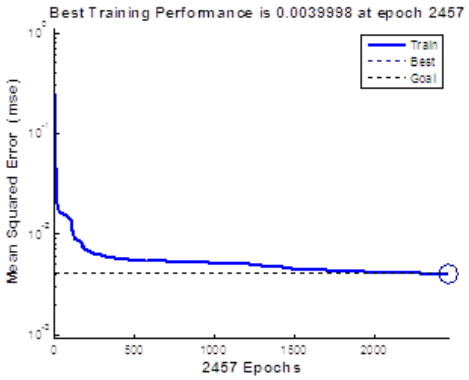

FIGURE 6 The results of training MSE

From the experimental result of the final gait recognition shown in Table 2, it can be concluded that we obtain a better gait recognition system which is based on BP neural network and plantar pressure. The accuracy of the gait recognition is more than 90% except for 'going upstairs' because of its complication among other three gaits.

TABLE 2 The result of final gait recognition

Gaits	True number of gaits	Classified number of gaits	Accuracy of the gait recognition
Standing	100	99	99%
Walking	100	90	90%
Jumping	100	91	91%
Going upstairs	100	85	85%

4 Discussions and conclusions

From the results of the final experiment, we obtain a high recognition rata as shown in the Table2. Consequently, using in-shoe wearable plantar pressure acquisition system to collect gait information is a good method for recognizing the types of gait with the function of classification of BP neural network. It can provide much more accurate gait information of human for the lower extremity exoskeleton of power assist robot, making the robot provide better services to help the human body.

Although we get a high recognition rate from the results of the final experiment, this is just a preliminary study, there are still many issues that need further study, such as finding a better algorithm to improve the recognition accuracy of 'going up-stairs', studying more complicate gait and so on. Thereby, there are lots of works to do to improve the accuracy rate of gain recognition.

Acknowledgment

This work was financially funded by National Training Programs of Innovation and Entrepreneurship for Undergraduates (Grand No.: G201410022041). And we would like to acknowledge that the four volunteers are studying in Beijing Forestry University.

Automatic verification of embedded system based on EFSM

Jinjiang Liu*, Jingjing Liang

School of Computer and Information Technology, Nanyang Normal University, Nanyang 473061, Henan Province, China

Received 6 July 2014, www.cmnt.lv

Abstract

To ensure the correctness of embedded system, automation of test case generation is necessary in industrial. This paper present a technique for specifying coverage criteria and a method for generating test suites for embedded systems whose behaviours is depend on its interactive environment. The embedded system under test can be described as extended finite state machines (EFSM) and the coverage criteria can be specified as monitor automata with parameters, which monitor and accept traces that cover a given test criterion of an EFSM. The flexibility of the technique is demonstrated by specifying a number of well-known coverage criteria based on control- and data-flow information using observer automata with parameters. We also develop a method for generating test cases from coverage criteria specified as observers. It is based on transforming a given observer automata into a bitvector analysis problem that can be efficiently implemented as an extension to an existing state-space exploration such as, e.g. SPIN or Uppaal.

Keywords: EFSM (Extended Finite State Machine), embedded system, test case generation, model-based testing

1 Introduction

A Model based test case generation has in recent years been developed as a prominent technique in testing of reactive software systems. A model serves both the purpose of specifying how the system should respond to inputs from its environment, and of guiding the selection of test cases, e.g., using suitable coverage criteria. Typical notations for such models are state machines in some form, often extended with data variables. Test cases can be selected as individual "executions" of the model, checking that the outputs from the system under test (SUT) conform to those specified by the mode.

In this paper, we present a technique for specifying coverage criteria in a simple and flexible manner, and a method for generating test cases according to such coverage criteria. The technique fits well as an extension of a state space exploration tool, such as, e.g., SPIN [2] or Uppaal [4], which performs enumerative or symbolic state-space exploration. It can also be used to generate monitors that measure the coverage of a specific test suite by monitoring the test execution.

Most related work on test case generation from models of reactive systems employs some rather specific selection of coverage criteria. Explicitly given test purposes have been considered, both enumerative [5-7] and symbolic [9]. Test purposes in these works can in some sense be regarded as coverage observers, but are not used to specify more generic coverage criteria and do not make us of parameterization, as in our work.

Some approaches present more flexible techniques for specifying a variety of coverage criteria. Hong et al [11-14] describe how flow-based coverage criteria can be expressed in temporal logic. A particular coverage item is expressed in CTL, and a model checker generates a trace, which covers the coverage item. In our approach, we use monitors instead of temporal logic, which avoids some of the limitations of temporal logic [15]. Our technique using monitors whit parameters can let one pass of a state-space exploration tool generate a test suite that covers a large set of coverage items, whereas the above approaches invoke a run of a model checker for each coverage item.

The remainder of the paper is structured as follows. We present EFSM in the next section, and monitors in Section 3. In Section 4-5, we show how our definitions of coverage can be used for test case generation, and report on a partial implementation of the technique. Section 6 concludes the paper

2 Extended finite state machine

In this section, it is assumed that a System Under Test (SUT) interacts with its environment through events. Whenever the SUT receives an input event, it responds by performing some local computation and emitting an output event. To a given SUT, we associate a set A of event types, each with a fixed arity. An event is a term of form *a(d1, . . . , dk)* where a is an event type of arity *k* and *d1, . . . , dk* are the parameters of the event. The set *A* of event types is partitioned into *input event types* and *output event types*. A trace is a finite sequence

$$a_1(\bar{d}_1)/b_1(\bar{d}_1') \quad a_2(\bar{d}_2)/b_2(\bar{d}_2') \ \ldots \ a_n(\bar{d}_n)/b_n(\bar{d}_n')$$

of *input/output event* pairs. Intuitively, the trace represents a behaviour where the SUT, starting from its initial state, receives the input event $a_1(\bar{d}_1)$ and responds with the

*Corresponding author's e-mail: nytcc@sina.com

output event $b_1(\bar{d}'_1)$. Thereafter, it receives the input event $a_2(\bar{d}_2)$ and so on. An input sequence is a finite sequence of input events.

Assume a set A_I of input event types, and a set A_O of output event types. An Extended Finite State Machine (EFSM) over (A_I, A_O) is a tuple $< L, L_0, \bar{v}, E >$ where:

1) L is a finite set of locations (control states).
2) $l_0 \in L$ is the initial location.
3) $\bar{v}$ is a finite set of state variables.
4) E is a finite set of edges, each of which is of form:

$$e : l \xrightarrow{a(\bar{w}), g \to \bar{u} := \overline{\exp r} / b(\overline{\exp r'})} l',$$

where e is the name of the edge, l is the source location, and l_0 is the target location. $a(\bar{w})$ is an input event type, and $\bar{w}$ is a tuple of formal parameters of event a, g is a guard, $u := \overline{\exp r}$ is an assignment of new values to a subset $\bar{u} \subseteq \bar{v}$ of the state variables, and $b(\overline{\exp r'})$ is an expression which evaluates to an output event.

Intuitively, an edge of the above form denotes that whenever the EFSM is in location l and receives an event of form $a(\bar{w})$, then, provided that the guard g is satisfied, it can perform a computation step in which it updates its state variables by $u := \overline{\exp r}$, emits the output event $b(\overline{\exp r'})$ and moves to location l'. We require the EFSM to be deterministic, i.e., that for any two edges with the same source location l and parameterized input event $a(\bar{w})$, the corresponding guards are inconsistent.

A system state is a tuple $< l, \sigma >$ where l is a location, and σ is a mapping from $\bar{v}$ to values. We can extend σ to a partial mapping from expressions over $\bar{v}$ in the standard way. The initial system state is the tuple $< l_0, \sigma_0 >$, where l_0 is the initial location, and σ_0 gives a default value to each state variable. A computation step is of the form $< l, \sigma > \xrightarrow{a(\bar{d}')/b(\bar{d}')} < l', \sigma' >$ consist of system state $< l, \sigma >$ and $< l', \sigma' >$, an input event $a(\bar{d}')$ and an output event $b(\bar{d}')$.Such that there is an edge of the (above) form $l \xrightarrow{a(\bar{w}), g \to \bar{u} := \overline{\exp r} / b(\overline{\exp r'})} l'$, for which $\sigma(g[\bar{d} / \bar{w}])$ is true, $\sigma' = \sigma[u \to \sigma(\overline{\exp r}[\bar{d} / \bar{w}])]$ and $\bar{d}' = \sigma(\overline{\exp r'}[\bar{d} / \bar{w}])$. A run of the EFSM over a trace $a_1(\bar{d}_1) / b_1(\bar{d}'_1) \ \ldots \ a_n(\bar{d}_n) / b_n(\bar{d}'_n)$ is a sequence of computation steps:

$$< l_0, \sigma_0 > \xrightarrow{a_1(\bar{d}_1)/b_1(\bar{d}'_1)} < l_1, \sigma_1 > \xrightarrow{a_2(\bar{d}_2)/b_2(\bar{d}'_2)} \cdots \xrightarrow{a_n(\bar{d}_n)/b_n(\bar{d}'_n)} < l_n, \sigma_n >,$$

labeled by the input-output event pairs of the trace.

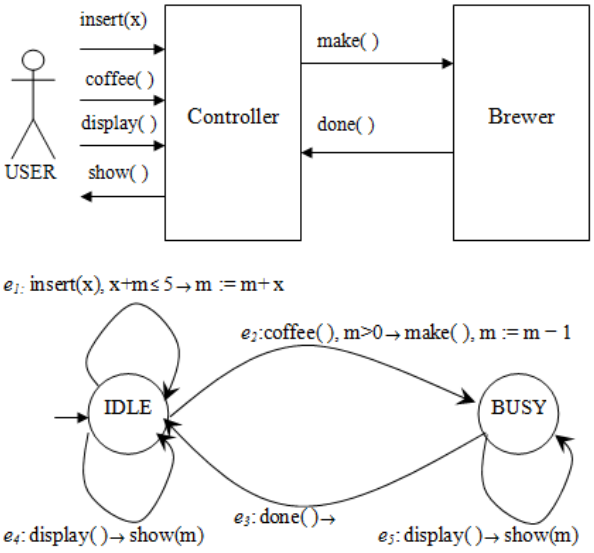

FIGURE 1 EFSM Model of the controller of a simple coffee machine

Example 1: an EFSM specifying for the simple coffee controller: Figure 1 demonstrates an EFSM specifying the behaviour of the controller of a simple coffee machine which interacts with a user and a brewer unit is shown. The controller has L = {*IDLE, BUSY*}, l_0 = *IDLE*, $\bar{v}$ = {m}, A_I = {*insert, coffee, display, done*}, A_O = {*show, make*}, and E = {e_1, e_2, e_3, e_4, e_5}. The parameter x and the variable m take values that are integers in the range [0 ... 5].

3 Monitors

In this section, we present how to use observers to specify coverage criteria for test generation or test monitoring.

As a very simple example, the coverage item "visit location l of the EFSM" can be represented by an monitor with one initial state, and one accepting location, named loc(l), which is entered when the EFSM enters location l. The coverage criterion "visit all locations of the EFSM" can be represented by a parameterized observer with one initial state, and one parameterized accepting location, named loc(L), where L is a parameter that ranges over locations in the EFSM. For each value l of L, the location loc(l) is entered when the EFSM enters location l.

Formally, an *monitor* is a tuple (Q, q_0,Q_f,B) where:

1) Q is a finite set of observer locations
2) q_0 is the initial observer location.
3) $O_f \in Q$ is a set of accepting locations, whose names are the corresponding coverage items.
4) B is a set of edges, each of form $q \xrightarrow{b} q'$, where b is a predicate that can depend on the input event received by the SUT, the mapping from state variables of EFSM to their values after performing the current computation step, and the edge in the EFSM that is executed in response to the current input event.

3.1 OBSERVER PREDICATE

In the following we introduce a more specific syntax for the predicates b occurring on observer edges. The predicates will use a set of predefined *match variables* that are given values at the occurrence of:

1) an event $a(\bar{d})$,

2) an edge $e: l \xrightarrow{a(\bar{w}), g \to \bar{u} := \overline{\exp r}} l'$ of the EFSM, traversed in response to $a(\bar{d})$,

3) the computation step $< l, \sigma > \xrightarrow{a(\bar{d})} < l', \sigma' >$ generated in response to $a(\bar{d})$.

For a traversed EFSM edge we use the following match variables (with associated meaning):

1) *event type* is the event type a of the occurring event;
2) *event-pars* is the list $\bar{d}$ of parameters of the event;
3) *edge* is the name *e*;
4) *target_loc* is the target location *l'*;
5) *guard* is the guard expression *g*;
6) *assignments* is the set *u* := $\overline{expr}$ of assignments;
7) *target_val* is the function from EFSM state variables to values.

To be able to express more interesting properties we also introduce a set of operations that can be used together with the match variables:

3.2 FUNCTION DEFINITION OF PREDICATE

With the match variables and operations above we define new functions that can be used as tests in the observer. In this paper, we shall make use of:

1) *def (v)* which is true *iff* the variable *v* is defined by the transition in the EFSM. This can be expressed as: $v \in map(lhs, assignments)$.

2) *use (v)* which is true *iff* the variable *v* is used (in a guard or assignment) by the transition in the EFSM. This can be expressed as: $v \in vars(map(rhs, assignments)) \vee v \in vars(guard)$.

3) *da* (v_1, v_2) which is true *iff* the variable v_1 is on the right hand side and variable v_2 is on the left hand side of the same assignment in the EFSM specification. The function can intuitively be understood to be true if v_1 directly affects v_2. This can be expressed as: $map\ (affect\ (v_1, v_2), assignments) \neq \varnothing$.

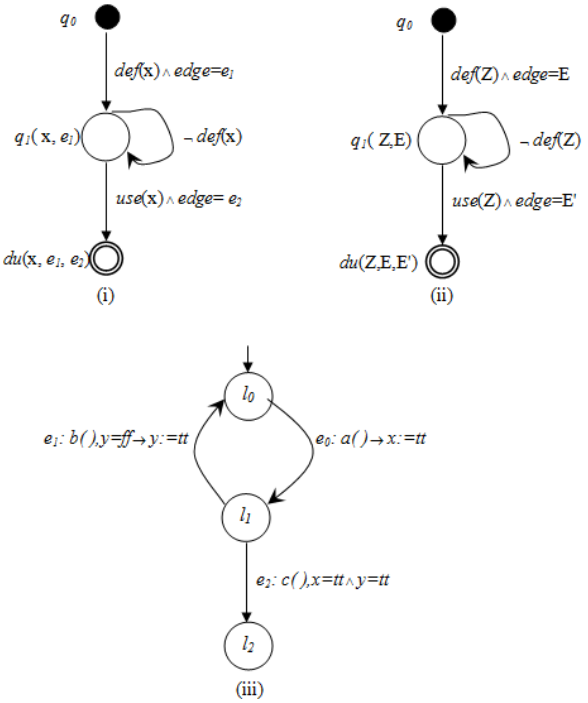

FIGURE 2 Examples of (i) a non-parameterized monitor (ii) a parameterized monitor, and (iii) a simple EFSM

Example 2: example for non-parameterized and parameterized monitor: apparently, the monitor in Figure 2(i) is non-parameterized which specifies definition-use pair coverage for a specific variable m, and specific edges e_1 and e_2. Figure 2(ii) shows a corresponding (parameterized) monitor that specifies definition-use pair coverage for any EFSM variable *Z*, and EFSM edges *E* and *E*'. This is done by parameterizing the location q1 with any variable and any edge, and the accepting location du with any variable and any two edges. The edges are parameterized in a similar way. For example, there is one observer edge from location $q_1(z, e)$ to location *du* (*z*, *e*, *e*') for each EFSM variable *z*, and each pair *e*, *e*' of EFSM edges.

4 Monitoring test generation by superposing a monitor on an EFSM

In test case generation or when monitoring test execution of a SUT, an observer observes the events of the SUT, and the computation steps of the EFSM. Reached accepting locations correspond to covered coverage items. We formally define the execution of an observer in terms of a composition between an EFSM and an observer, which has the form of a superposition of the observer onto the EFSM. Each state of this superposition consists of a state of the EFSM, together with a set of currently occupied observer locations.

Say that a predicate *b* on a monitor edge is satisfied by a computation step $< l, \sigma > \xrightarrow{a(\bar{d})} < l', \sigma' >$ of an EFSM, denoted $< l, \sigma > \xrightarrow{a(\bar{d})} < l', \sigma' > \models b$ if *b* holds for the

event $a(\bar{d})$, the computation step $<l,\sigma> \xrightarrow{a(\bar{d})} <l',\sigma'>$ and the edge $e: l \xrightarrow{a(\bar{w}),g \to \bar{u}:=\overline{\exp r}} l'$ from which the computation step is derived.

Formally, the superposition of an monitor (Q, q_0, Q_f,B) onto an EFSM < L,L_0, $\bar{v}$,E >is defined as follows.

1) *States* are of the form $<<l,\sigma>||Q>$, where $<l,\sigma>$ is a state of the EFSM and Q is a set of locations of the monitor.

2) The *initial state* is the tuple $<<l_0,\sigma_0>||\{q_0\}>$, where $<l_0,\sigma_0>$ is the initial state of the EFSM and q_0 is the initial location of the monitor.

3) A *computation step* is a triple $<<l,\sigma>||Q> \xrightarrow{a(\bar{d})} <<l',\sigma'>||Q'>$ such that $<l,\sigma> \xrightarrow{a(\bar{d})} <l',\sigma'>$ and

$$Q' = \{q' \mid q \xrightarrow{b} q' \text{and } q \in Q \text{ and } <l,\sigma> \xrightarrow{a(\bar{d})} <l',\sigma'> \models b\}.$$

4) A state $<<l,\sigma>||Q>$ of the superposition *covers the coverage item* represented by the location $q_f \in Q_f$ if $q_f \in Q$.

$$<<l_0,\{x=tt,y=tt\}>|| \{q_0,q_1(x,e_0),q_1(y,e_1)\}> \xrightarrow{a()} <<l_1,\{x=tt,y=tt\}>||\{q_0,q_1(x,e_0),q_1(y,e_1)\}>$$

5 Experimental results for three crucial embedded systems

5.1 ALGORITHM

At test case generation, we use the superposition of an observer onto an EFSM, and views the test case generation problem as a search exploration problem. To cover a coverage item q_f is then the problem of finding a trace $tr = <<l_0,\sigma_0>||\{q_0\}> \xrightarrow{a(\bar{d}) \cdots a'(\bar{d}')} <<l,\sigma>||Q>$, such that $q_f \in Q$.

An abstract algorithm to compute test case is shown as below:

1) $Pass := \varnothing$, Max:=0, $w_{max} := w_0$
2) $Wait$:={ $<<s_0||\{q_0\}>,w_0>$ }
3) **while** Wait $\neq \varnothing$ **do**
4) select $<<s||Q>,w>$ from $Wait$
5) **if** $|q_f \cap Q| > Max$ **then**
6) $w_{max} := w$, Max:= $|q_f \cap Q|$
7) **if** for all $<s||Q'>$ in $Pass$: $Q \subsetneq Q'$ **then**
8) add $<s||Q>$ to $Pass$
9) for all $<s''||Q''>$
10) such that $<s||Q> \xrightarrow{a} <s''||Q''>$:
11) add $<<s''||Q''>,wa>$ to $Wait$
12) **return** w_{max} and Max

To improve the presentation, we use s to denote a system of the form $<l,\sigma>$ and s_0 to denote the initial system state $<l_0,\sigma_0>$ and a to denote an input action $a(\bar{d})$. The algorithm computes the maximum number of coverage items that can be visited (*Max*), and returns a trace with maximum coverage (w_{max}). The two main data structures *Wait* and *Pass* are used to keep track of the states waiting to be explored, and the states already explored, respectively.

Initially, the set of already explored states is empty and the only state waiting to be explored is the extended state $<<s_0||\{q_0\}>,w_0>$, where w_0 is the empty trace (in Line2). The algorithm then repeatedly examines extended states from Wait (in Line 3). If a state <s||Q> found in *Wait* is included in a state <s||Q> in *Pass*, then obviously <s||Q> does not need to be further examined(in Line 7-8). If not, all successor states reachable from <s||Q> in one computation step are put on Wait, with their traces extended with the input action of the computation step from which they are generated (in Line 9-11). The state <s||Q> is saved in *Pass*. The algorithm terminates when *Wait* is empty.

The variables w_{max} and *Max* are initially set to the empty trace and 0, respectively (in Line 1). They are updated whenever an extended state is found in *Wait* which covers a higher number of coverage items than the current value of *Max* (in Line 5-6). Throughout the execution of the algorithm, the value of *Max* is the maximum number of coverage items that have been covered by a single trace, and w_{max} is one such trace. When the algorithm terminates (in Line 12), the two values *Max* and w_{max} are returned.

5.2 BITVECTOR IMPLEMENTATION

In order to efficiently represent and manipulate the set Q of observer locations we shall use bitvector analysis [15]. Let the set Q be represented by a bitvector where each bit represents an observer location q'. Then each bit is updated by the following function:

$$f_{q'}(q') = \bigvee_{<b,q> \in in(q')} q \wedge b ,$$

where $in(q') = \{<b,q> \mid q \xrightarrow{b} q' \in B\}$ is the set of pairs of predicates b and source locations q of the edges ingoing to the location q'. That is, given a state of the superposition $<<l,q>||Q>$ and an EFSM transition $<l,\sigma> \xrightarrow{a(\bar{d})} <l',\sigma'>$ the bit representing q' is set to 1 if there is an monitor edge $q \xrightarrow{b} q' \in B$, such that $q \in Q$ and $<l,\sigma> \xrightarrow{a(\bar{d})} <l',\sigma'> \models b$. Otherwise the bit representing q' is set to 0. It should be obvious that this

corresponds precisely to the semantics of an monitor superposed onto an EFSM, described in Section 4.2

Example 4: Interpreting monitor states set Q into bitvector: when the monitor in Figure 2(ii) is superposed onto the EFSM in Figure 2(iii), we have: $E = E' = E = \{e_0, e_1, e_2\}$ and $Z = \bar{v} = \{x, y\}$. Thus, we have that:

$$Q = \{q_0\} \cup \{q_1(z, e_a) \mid z \in \bar{v} \wedge e_a \in E\} \cup \{du(z, e_a, e_b) \mid z \in \bar{v} \wedge e_a \in E \wedge e_b \in E\}.$$

Any enumeration of the set can be used as index in the bitvector. As the observer has three locations with parameters we get three types of bitvector functions:

$$f_{q_0}(q_0) = q_0 \wedge tt, \quad (1)$$

$$f_{q_1(v_i, e_j)}(q_1(v_i, e_j)) = (q_0 \wedge def(v_i) \wedge edge = e_j) \vee (q_1(v_i, e_j) \wedge \neg def(v_i)), \quad (2)$$

$$f_{du(v_i, e_j, e_k)}(du(v_i, e_j, e_k)) = (q_1(v_i, e_j) \wedge use(v_i) \wedge edge = e_k) \vee (du(v_i, e_j, e_k) \wedge tt). \quad (3)$$

There is one function of Equation (1), six of Equation (2), and 18 of Equation (3). Note that Equation (1) is always true and that Equation (3) will remain true once it becomes true, due to implicit self-loops in these locations.

6 Conclusion

This paper has presented a technique for testing the remote environment control systems. Our technique have shown to be a flexible tool in model checking and run-time monitoring, and by this paper we have shown that they are a versatile tool for specifying coverage criteria for test case generation and test monitoring.

In particular, the parameterization mechanism, as used in this paper, allows a succinct specification of several standard generic coverage criteria. In this way, test case generation can be transformed into a reachability problem, which can be general used in verification of environmental control systems.

Abstract

Based on the distinct element and moment tensor theory, the damage process and mechanism of rock sample with circular hole were researched. The crack evolution patterns corresponding to the laboratory test showed that there were mainly four stages. Firstly, the microcracks were randomly distributed in the rock sample. Secondly, the larger primary cracks are formed around top of circular hole with the increasing of microcracks. Then, more microcracks were localized near the boundary of circular hole, which formed the competition of several possible sets of fractures. Finally, the rupture zone was formed along one of crack zones. The size effect of circular hole showed that there would take on different rupture forms with increasing of diameter. Meanwhile, for better probing into damage mechanism, the acoustic emission (AE) algorithm based on moment tensor theory was implanted into the whole loading process. The AE magnitudes of all parts of rock sample were shown in AE contour maps, and these contour maps showed that the formations of rupture zone were contributed by different stress or energy levels.

Keywords: circular hole, damage mechanism, acoustic emission, distinct element, moment tensor

1 Introduction

There has been a substantial effort by engineers to probe into the damage and fracture propagation around underground excavations. It is generally thought that, for a circular opening in a brittle rock subjected to different stress fields, there mainly exist three types of fracture: spalling fracture caused by compressive stress field, primary fracture caused by tensile stress field, and remote fracture caused by mixture effect of compressive and tensile stress field [1-3]. For further understanding the damage process, various research methods were employed and developed. One approach often used is to build theoretical models and find analytical solutions. Sharan [4] finished the analytical solution for stress and displacement around a circular opening in a generalized Hoek-Brown rock. Zhang [5] obtained the stress and deformation solution of circular opening in strain-softening rock mass. In addition, the effect of seepage force was considered in the theoretical models [6, 7]. Although the analytical methods can facilitate us to understand the mechanical mechanism of deformation and failure characteristics from perspective of continuum mechanism, after all, some of results are lack of evidences from field and laboratory experiments [8], and cannot easily probe into the entire fracture process from meso-scale. Therefore, the physical test and numerical simulation methods are adopted by many researchers in recent years. However, some of simulation works focused on the loading type failure of Berea sandstone and didn't consider the size effect of circular hole [9, 10]. As we know, the lithology and size effect of circular hole would influence on the rupture characteristic. With respect to the simulation method, the distinct element method would be more practical in modelling the entire fracture process, which involves the initiation, propagation, and coalescence of micro-cracks through to the formation of a full-scale macro-crack in the rock materials [11], compared other methods like fast lagrangian analysis of continua or finite element method [10, 12]. Because mesh discretization is not necessarily considered in this way, namely the mesh sensitivity problem is not present.

For these reasons, take the previous laboratory experiment done by Lv [13] as reference, the aim of our work is to further reveal progressive failure leading to collapse around a circular opening in granite specimen by virtue of simulation of particle flow code (PFC2D). The opening size effect is considered. Meanwhile, for better understanding the damage process and mechanism, the acoustic emission (AE) algorithm based on the moment tensor theory is used in the simulation.

2 Laboratory experimental model

The rock samples used in the test were granite materials which were obtained from Dagangshan Hydropower Station in Sichuan Province of China. The uniaxial compression strength is 195MPa, the Young's modulus is 47.6GPa, the Poisson ratio is 0.23, and the tensile strength is 6.2MPa. To simulate the underground opening,

[*]***Corresponding author*** e-mail: lch@ustb.edu.cn

rectangular rock plates containing a 10mm diameter hole in centre were tested in servo-controlled hydraulic test machine (type: RMT-150C). The size of the rock plate was designed to 60 mm × 20 mm × 120 mm (length, width, height). Then the rectangular rock plates with a circular opening were loaded to failure under uniaxial compression test. Partial experimental results finished by Lv [13] are listed above. Figures 1a, 1b, 1c shows the failure process of rock plate, which represents the initiation of primary cracks, the expanding of remote cracks and compression-shear cracks, and the generation of rupture zone due to the coalescence of cracks respectively. Figure 2 shows the variation of compressive stress and AE events with axial strain.

3 Establishment of numerical model and loading test

PFC2D is a distinct element computer program designed to simulate the mechanical behaviour of bonded or unbounded granular materials. Therefore the rock sample can be treated as assembly of circular particles that can interact through normal and shear springs. Although PFC2D can simulate a particulate media, any circular element in this program does not necessarily model a particle in the real material as two-dimensional nature of the program limits particles to disks or cylinders [9]. So we used this software as an attempt to mimic the basic mechanical features of actual material.

Before establish the numerical rock sample, numerical calibration test were necessary [14]. The micro-mechanical parameters were needed to be adjusted repeatedly, and finalized until the macroscopic properties such as Young's modulus and the uniaxial compressive strength calculated are basically consistent with physical macroscopic parameters.

The micro-parameters required to be adjusted are as follows: ρ is ball density, $R_{\min}$ is minimum ball radius, R_ratio is ball size ratio, $\overline{\lambda}$ is parallel-bond radius multiplier, E_c is ball-ball contact modulus, $\overline{E_c}$ is parallel-bond modulus, k_n / k_s is ball stiffness ratio, $\overline{k}_n / \overline{k}_s$ is parallel bond stiffness ratio, μ is ball friction coefficient, $\overline{\sigma}_c$ is parallel bond normal strength, and $\overline{\tau}_c$ is parallel-bond shear strength. The values of micro-parameters are listed in Table 1.

TABLE 1 Micro-mechanical parameters of numerical samples

$\rho/(kg.m-3)$	$R_{\min}$ / (mm)	R_ratio	μ	
2500	0.3	2.0	0.5	
$\overline{\sigma}_{mean}$ / (MPa)	$\overline{\tau}_{mean}$ / (MPa)	$\overline{\sigma}_{sdev}$ / (MPa)	$\overline{\tau}_{sdev}$ / (MPa)	
100	100	36	36	
k_n / k_s	$\overline{k}_n / \overline{k}_s$	E_c / (GPa)	$\overline{E_c}$ / (GPa)	$\overline{\lambda}$
2.5	2.5	37.6	37.6	1.0

There are mainly four steps for the creation of corresponding rock samples according to the micromechanics parameters that have been determined by calibration tests. Firstly, a rectangular specimen consisting of arbitrarily placed particles confined by four frictionless walls is generated by radius expansion method. Secondly, radii of all particles are changed uniformly to achieve a specified isotropic stress so as to reduce the magnitude of locked-in stresses that will develop after subsequent bond-installation and specimen-unloading steps. In this paper the isotropic stress is set to 0.1MPa. Thirdly, the floating particles that have less than three contacts are eliminated. Fourthly, the parallel bonds are installed throughout the assembly between all particles that are in near proximity to finalize the specimen.

As the generation of rock sample was completed, then circular holes with diameter from 10mm to 50mm were excavated respectively since the size effect of circular hole on failure characteristic of rock sample would be researched. In addition, the AE algorithm was implanted into the whole failure process for recording the AE event and magnitude.

4 Acoustic emission algorithm based on moment tensor theory

There are essentially two ways that have been adopted to extract seismic or AE information from bond breakages in PFC [15-17]. Initially, the magnitude of AE events from the kinetic energy of the particles in each crack was calculated, and moment tensor was also calculated from the force at the contact as breakage of bond occurs. However, this method often yields magnitudes that are too large. Besides, it fails to account for shear events where the entire force at the contact is not lost. For solving the problem, the moment tensor of AE events was recalculated by observing the force changes at contacts around the source particles, and moment magnitudes were then

calculated form the moment tensor matrix. Therefore the second computing method was used in this paper to further probe into the damage mechanisms of rock samples with circular hole.

The Equation for calculating a moment tensor for an AE event is as following:

$$M_{ij} = \sum_{S} \Delta F_i R_j , \tag{1}$$

where ΔF_i is *i*-th component of the change in contact force, and R_j is *j*-th component of the distance between the contact point and event centroid. The centroid of the event is assumed to be the geometric centre of multiple-crack events since each AE event could be composed of more than one bond breakage. The sum is performed over source boundary which is a surface that completely encloses the displacement discontinuity caused by the 'fault'. As we know the moment tensor is a function of time because it will be calculated at each time step over the duration of the event. The duration of AE event is determined by assuming a fracture propagates at half the shear wave velocity of the rock. Therefore, for reducing memory consumption, the final moment tensor that is independent of time is determined to be the moment tensor at the time of maximum scalar moment. The formulation of the scalar moment is as following:

$$M_0 = \left(\frac{\sum_{j=1}^{3} m_j^2}{2} \right)^{1/2} , \tag{2}$$

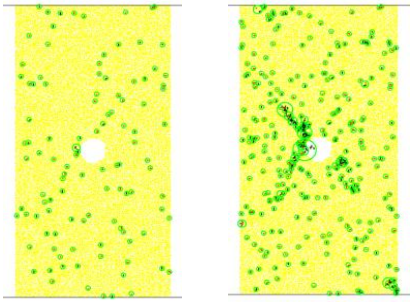
where m_j are the eigenvalues of the moment tensor matrix. By virtue of the scalar moment, the moment magnitude of the event can be calculated by this following Equation:

$$M_w = \frac{2}{3} \log M_0 - 6 \tag{3}$$

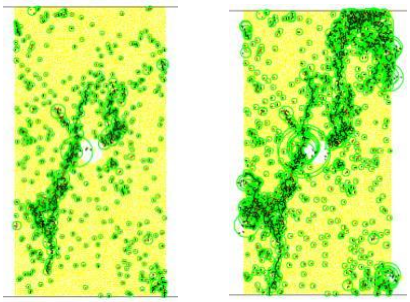
5 Numerical experiment results and discussion

5.1 CRACK EVOLUTION AND AE CHARACTERISTIC

Figure 3 shows the numerically simulated failure process around a circular opening with diameter 10 mm. The black and red spots represent the bond breakage as the result of its normal and shear strength being exceed respectively. Each green circle represents an AE event, and its radius represents the range of AE event, i.e. one AE event may contain many bond breakages. At the beginning loading stage (Figure 3a), there are some independent microcracks (bond breakages) distributed randomly in the rock sample, which lead to the production of AE events. In this period, most of AE events consist of a series of single microcrack event, only few are made up of more than one microcrack events. In the second stage (Figure 3b, axial strain is about 1e-3), it can be observed that more microcracks are generated in the rock sample, and the larger primary cracks are formed around top of circular hole. As the axial strain is getting to around 1.5e-3 (Figure 4), more microcracks localize near the lateral boundaries of the circular opening and begin to form rupture zones on both sides of specimen (Figure 3c). Meanwhile, the remote cracks are produced and expanded. The number of AE events starts to increase, and the radius of some green circles have become larger, which means the larger scale cracks form, and magnitudes of partial AE events also become increasingly. Finally, as the axial strain gets to around 2e-3, the rock sample shows a macroscopic discontinuity along the rupture zone (Figure 3d), and the number of AE events gets to the maximum nearby the peak of loading stress (Figure 4).



(a) Random damage (b) Local damage



(c) Damage expanding (d) Rupture zone

FIGURE 3 Simulated failure process of rock sample

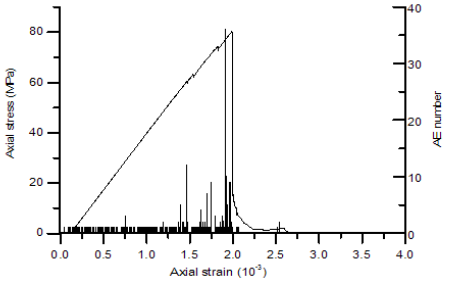


FIGURE 4 Simulated compressive stress and AE event number versus axial strain

The Figure 5 demonstrates the contour map of moment magnitude of AE event, which is corresponding to the Figure 3d. As we can see, the magnitudes of main rupture zone represented by red colour are between -4.9 and -4.7 which means such kind of magnitude can fully satisfy the

generation of rupture zone developed by the coalescence of the microcracks. Outsides of main rupture zone, the magnitudes are mainly between -5.5 and -5, which means these smaller scale damages fail to connect each other to produce the larger scale cracks. In short, such kind of simulation based on the distinct element and moment tensor theory can better reveal and demonstrate the damage process and mechanism of rock sample. The results of magnitude calculated by scalar moment match very well with simulated damage distribution and actual lab test.

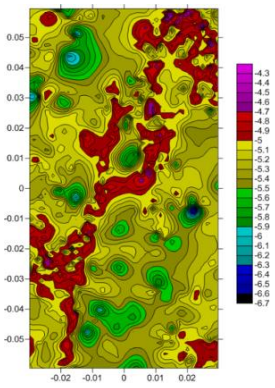

FIGURE 5 Contour map of magnitude of AE event

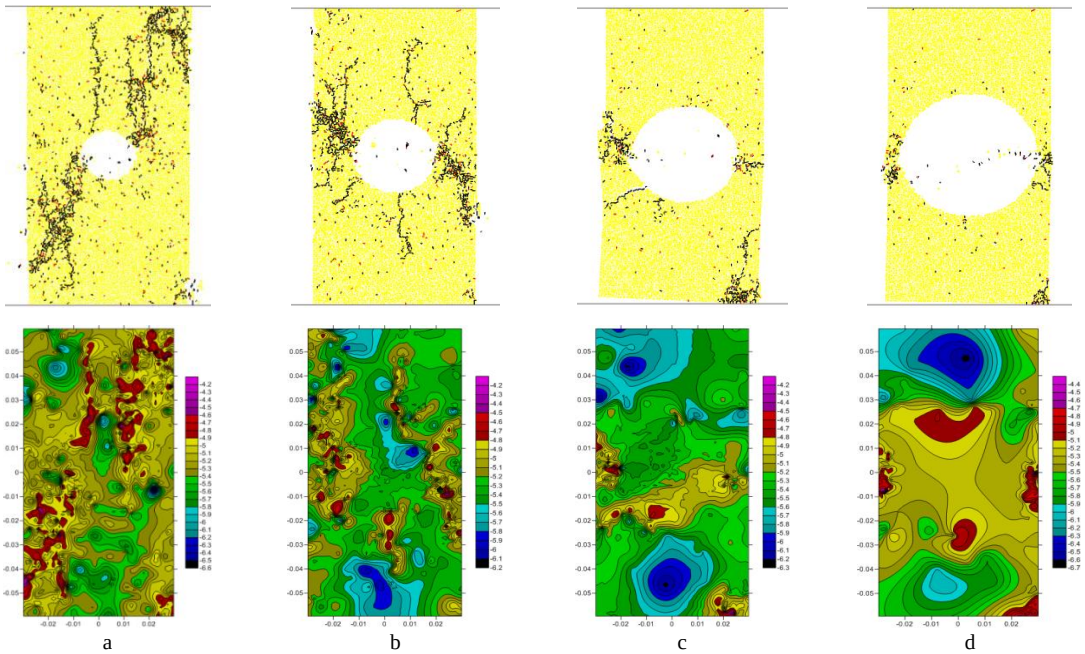
Although the simulated curve of compressive stress versus the axial strain shows a slightly stiffer response, the whole variation trend and peak value are basically in agreement with the actual laboratory test. As for number of AE events versus axial strain, the variation trend also has similarity with actual lab test despite of concrete number of AE event, because we only care about basic mechanical features and laws.

5.2 THE SIZE EFFECT OF CIRCULAR HOLE

The influences of different sizes of circular hole on the final rupture zones of the rock sample are considered in this section. As the diameters are between 10 mm and 30 mm (Figure 3d, Figures 6a-6b), there are longitudinal crack zones generated nearby the top or bottom of the circular hole, especially for the diameter 30 mm, because the increment of size of circular hole reduces the tensile strength on the periphery of hole, and the values of tensile stress on the top and bottom of hole are also larger than other direction. However, more microcracks localize near the lateral boundaries of the circular hole and form notches, and finally the failure plane extends from the notches in the inclined direction; As the diameters are greater than 40mm, the rock sample shows the symmetrical failure along the rupture zone of which the direction is sub-horizontal.

It is interesting to note that the maps of contour of magnitude of AE event, there still take on red colour in the core area of rupture zones. However, periphery of red colour is mainly encompassed by the yellow colour, part of which is still in the rupture zone, and of which the magnitudes are lower than red colour. Such kind of phenomenon is more obvious as the diameter of circular hole is greater than 20 mm. There are mainly two reasons we think lead to this kind of phenomenon.



a b c d

FIGURE 6 Crack patterns of rock sample and contour maps of magnitude of AE event and under different diameters of circular hole including 20 mm, 30 mm, 40 mm, 50 mm

It is interesting to note that the maps of contour of magnitude of AE event, there still take on red colour in the core area of rupture zones. However, periphery of red colour is mainly encompassed by the yellow colour, part of which is still in the rupture zone, and of which the magnitudes are lower than red colour. Such kind of phenomenon is more obvious as the diameter of circular hole is greater than 20 mm. There are mainly two reasons we think lead to this kind of phenomenon. On the one hand, the different stress or energy levels can come together to promote propagation of the rupture zone. Some core ruptures are mainly finished by the higher magnitude of stress or energy then the lower stress or energy finishes extension and coalescence of the rupture zone on the basis of core rupture zone. On the other hand, the increasing of size of circular hole equivalently increases the damage degree of rock sample and decreases the compressive strength as we can see from the Figure 7, which make the relatively lower stress or energy easier to generate the cracks.

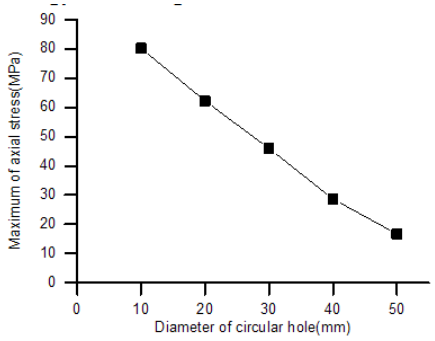


FIGURE 7 the maximum of axial stress versus the diameter of circular hole

6 Conclusions

In this study, the failure process of granite sample with circular hole was simulated by the distinct element method. The numerically simulated results reproduced the development of cracks around a circular opening in rock, which were in very agreement with the laboratory test and also can reveal microscopic damage characteristic. The microcrack pattern showed that competition of several possible sets of fractures, eventually the cracks on both sides of circular hole prevailed and continued to propagate until the final rupture zone was formed. The simulated number of AE events would get peak as failure occurred, which was consistent with actual test.

The AE algorithm based on the moment tensor theory was used in the simulation, which can better reveal the damage mechanism for the loading test. Especially, the AE magnitude contour map can tell us intuitively the damage degree in different parts of rock sample.

The size effect of circular hole was considered in this paper. It showed that the crack development and distribution were influenced by the size of diameter, because the size of circular hole determines the prefabricated damage degree of the rock sample. In addition the contour map of AE magnitude showed that the formation of rupture zone were contributed by different stress or energy levels, and it would be more obvious with increasing of size of circular hole.

Abstract

Kohonen neural network recognizes and clarifies substantive network data, but with a long running time and a slow convergence process. To solve this problem, a network intrusion clustering method is presented in this paper. Specifically, the training data is pretreated using Fuzzy C-Means (FCM). Then some selected data will be trained with using Kohonen neural network. Meanwhile, to speed up the convergence process of Kohonen neural network and to form a better optimized network topology, a neighbourhood function is established for the competing neuron. Each neuron has neighbourhood topology collections. The data simulation results demonstrate the efficiency and effectiveness of the proposed algorithm.

Keywords: Kohonen neural network; neuron, FCM, network intrusion clustering

1 Introduction

Network intrusion is an unauthorized access to the completeness, privacy and availability of a computer or network. Intrusion detection is an intrusion detection system that attempts to discover unauthorized malicious activity by analysing information collected by the computer or network. Kohonen neural network (KNN) is applied to the detection of network intrusion. The improvement of KNN can be achieved by a set suitable threshold to the competition layer in the neural network to avoid the occurrence of necrotic neuron [1]. Also fuzzy bias degree is introduced in some documents, which aims to avoid dead neurons [2]. To speed up the convergence process of KNN, energy function is introduced [3]. An initial value is set by a simple splitting algorithm to improve KNN. The more data it has, the longer time KNN training will take. To speed up the process, each kind of training is FCM clustered. Data is chosen according to the degree of membership for KNN training. Meanwhile, KNN will be improved in two aspects. One is neighbourhood function established among neurons, and the other is topology identification of neural neighbours, in which the training data, after being correctly clarified, reach suitable topology and then the iteration breaks.

2 FCM

FCM is a cluster algorithm based on objection function. It is developed from Hard C- Means (HCM). It is a algorithm that determines the likelihood of a data by using the membership degree. If X is a vector of a limited data set in eigenspace R^N. According this algorithm, X is divided into several fuzzy cluster, each centre vector forms a set $V=\{v_1, v_2, \cdots v_c\}$, a matrix of $N\times C$ dimension $U=(u_{ij})$, $u_{ij}\in[0,1]$, a membership matrix of each sample, and here $i=1,2,...,N;\ j=1,2,...,C$ makes the fuzzy objective function minimum. Fuzzy clustering objective function is presented in Equation (1) and Equation (2).

$$J=\sum_{i=1}^{N}\sum_{j=1}^{C}u_{ij}\left\|x_i-v_j\right\|^2, \tag{1}$$

$$u_{ij}=\begin{cases}\left[\sum_{k=1}^{c}\dfrac{\left\|x_i-v_j\right\|^{\frac{2}{m-1}}}{\left\|x_i-v_k\right\|^{\frac{2}{m-1}}}\right]^{-1} & \left\|x_i-v_k\right\|\neq 0\\ 1 & \left\|x_i-v_k\right\|=0\&\&k=j\\ 0 & \left\|x_i-v_k\right\|=0\&\&k\neq j\end{cases}. \tag{2}$$

$$v_j=\frac{\sum_{i=1}^{n}u_{ij}^m x_i}{\sum_{i=1}^{n}u_{ij}^m}$$

Here, u_{ij} is the degree of membership for the x_i in cluster j, m is the fuzzy weight index, v_j is the centre vector for cluster j.

FCM algorithm schema:

Step 1: fix discriminant function C, and fuzzy weight index m.

Step 2: initial centre vector for cluster v.

[*]***Corresponding author*** e-mail: aboyhw@163.com

Step 3: compute the membership matrix *u*.

Step 4: compute each cluster centre *v*.

Step 5: compute the fuzzy cluster objective value to determine if it meets the given termination conditions. If it meets, the iteration ends. If not, jump to step 3.

3 Modified Kohonen neural network

The model was first described as an artificial neural network by the Finnish professor Teuvo Kohonen in 1981, and is sometimes called a Kohonen map or network. It is sometimes called SOFM [5]. It automatically gets the centre of each cluster by competitive learning training coefficient, so it is widely used in fields like pattern identification and patter control. Kohonen believes that neurons in different part do their own jobs [6]. Different parts of the network will respond accordingly to certain input patterns. Kohonen network can learn both the distribution characters and the topology structure of input vector of training data [7, 8]. Typical structure of KNN is shown in Figure 1.

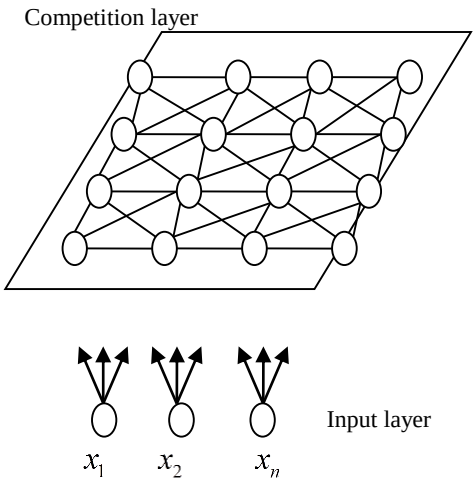

FIGURE 1 The structure of KNN

The training algorithm for the Kohonen network as follows:

(1) Initialise the weight vectors, $w_j(0)$,where j is an index denoting the neuron number and runs form 1,2,…,*K*, where *K* is the total number of neurons int the output grid. The number in () afterwards is used to denote the time-step. The weight vectors can be initialised by setting each component of each weight vector to a small random number.

(2) Draw a connection vector, $X=(x_1,x_2,\cdots x_m)^T$, from the training data without replacement.

(3) Find the winning neuron, j^* ,This is the neuron whose weight vector is closed to *X* in a Euclidean sense, calculated as follows:

$$d_j=\|X-W_j\|=\sqrt{\sum_{i=1}^{m}(x_i(t)-w_{ij}(t))^2}\ .$$

(4) Adjust the weight vectors of all neurons, as follows:

$$\triangle w_{ij}=w_{ij}(t+1)-w_{ij}(t)=\eta(t)(x_i(t)-w_{ij}(t))$$

where $\eta(t)$ is the learning rate at epoch number *t*, usually $\eta(t)=\frac{1}{t}$ or $\eta(t)=0.2\left(1-\frac{t}{T}\right)$, *T* is the total number of training.

(5) Repeat from step 2 until all training examples have been presented. This constitutes on epoch.

Repeat form step 2 until the desired number of epochs is reached.

According to the biology principal of neurons, neurons will be in a sorted order after self-organized training. Neurons of the same class will be next to each other, while those different will be in a distant [9-12], as Figure 2 shows. For example, a competition layer with 4 rows and 4 columns has 16 neurons. Among them, number 1 is the winning neuron, and then number 2 and number 5 neurons is more possible to win. But number 16 neuron is not likely to win. So, the first a probability matrix needs to be established for each neuron before network training.

$$B=\begin{bmatrix} b_{11} & b_{12} & \cdots & b_{1n} \\ b_{21} & b_{22} & \cdots & b_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ b_{n1} & b_{n2} & \cdots & b_{nn} \end{bmatrix},$$

where, b_{ij} is the transit probability between the *i*-th neuron and the *j*-th neuron. $i=1,\ldots,n$, $j=1,\ldots,n$. Here *n* is the total amount of the neurons in the competition layer. Then the neighbourhood function $G(t)$, follows a Gaussian probability distribution as defined by Equation (3), where $j(t)$ denotes the neuron in the neighbourhood of the winning neuron, and then adjust the weight vectors of all neurons as given in Equation (4).

$$G(t)=\exp\left(-\frac{\left(j(t)-j^*\right)^2}{2}\right), \tag{3}$$

$$Vw_{ij}=w_{ij}(t+1)-w_{ij}(t)=g(t)\eta(t)(x_i(t)-w_{ij}(t))\ . \tag{4}$$

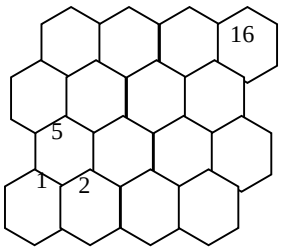

FIGURE 2 Topology of neurons in competition layer with 4 ×4

Identification of neighbour topology. Build a neighbour set U for each neuron. For example, the

neighbour set of number 1 neuron is {2,5}, and number 5 is {1,2,6,9,10}. In the process of KNN training, we set minimum learning times. If the training times exceed the set one, KNN begins to self-classification and identification with the aim to see if the neurons are correctly classified. For example, in a competition Kohonen neural network with 6 rows and 6 columns, there are 5 training kinds. The winning neuron in each kind forms a set, namely {6,12}, {7,13}, {16,21,22}, {25,31}, {30,36}. Take the intersection of each two sets. If all of them are disjoint, then it shows that KNN can classify correctly. At the same time, conduct neighbourhood topology identification.

4 Simulation results

4.1 GET DATA

Intrusion Detection has become a pertinent part of network security. An Intrusion Detection System can monitor the events happening in a system, and identify whether they are attacks or legitimate accessed. There are nine 'basic features' in Intrusion Detection System, such as duration of the connection; total bytes sent to destination host; total bytes sent to source host; service type ,such as FTP, HTTP, Telnet; number of wrong fragments. In our experiment, we get five attack categories as shown in Table1.

TABLE 1 Category attack data use by our experiment

Category	Description
1	HTTP
2	FTP
3	Mail
4	SQL
5	Remote shell

4.2 FILTER DATA

The attack dataset is $N_{4500\times39}$, we use the 4000 data as the training data, the lest 500 as the test data. Each given 5 classified 4000×38 training data is FCM clustered. A membership matrix of each data will be formed. Arrange the matrixes in the order of membership degree. Choose the first 20 data as representatives. The algorithm of FCM clustered is described as Algorithm 1.

Algorithm 1:Filter data using FCM

Input: $N_{4500\times39}$

Output: $\text{TrainData}_{100\times38}$

```
for i=1:category
{
DataIndex=find(T1==i);
data=inputn(DataIndex,:);
[center,U,obj_fcn] = fcm(data,1);
[su,index]=sort(U,'descend');
FilterData{i,:}=inputn(DataIndex(index(1:20)),:);
}
TrainData=[FilterData{1,1};FilterData{2,1};
FilterData{3,1};FilterData{4,1};FilterData{5,1}];
```

4.3 TRAINING KNN

We get a training data of 100×38. The dimension of the data is 38 from 5 different network invasion patterns. So there are 38 nodal points in the input layer. The nodal point in the competition lay represents the potential kinds of the input numbers. Usually the nodal point in the in the competition is far more than the actual data kinds. Here the author assumes the nodal point is 36 and the neuron topology arrangement is as shown in Figure 3.

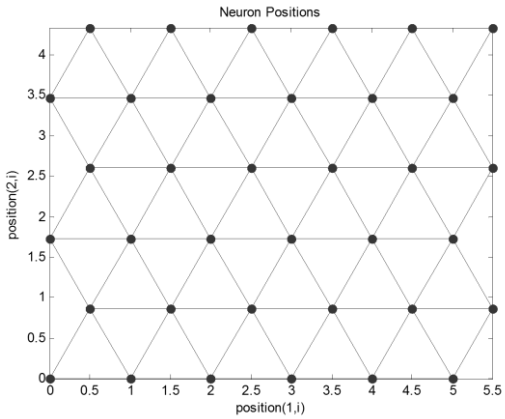

FIGURE 3 Topology arrangements of neurons in the competition layer

The data will be trained by the modified KNN (MKNN). The Process of simulation experiments as shown in Figure 4. The winning neurons's topology arrangement is as shown in Figure 5.

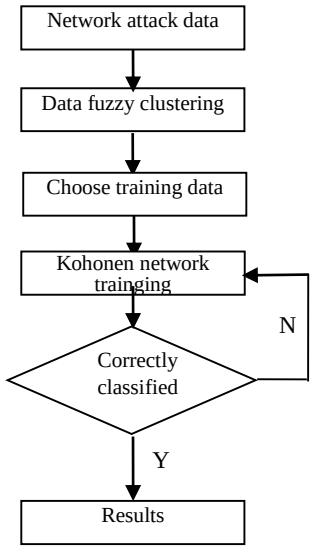

FIGURE 4 Process of simulation experiment

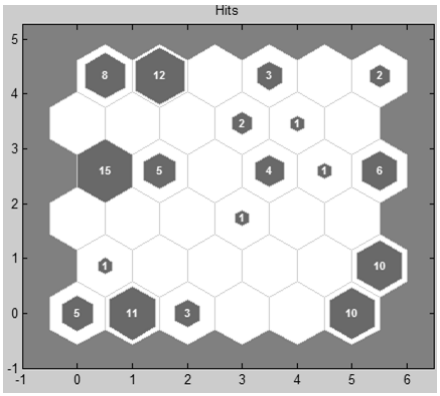

FIGURE 5 The winning neuron topology

The List of winning neurons as shown in Table 2.The computer adopted in the experiment is Intel Core i3-2370M 2.4G with 6G RAM and a runtime environment of Matlab R2012b. It takes the traditional KNN 30 minutes and 42 seconds to deal with the training data, while only less 5 minutes using the method mentioned in this essay and the topology of the winning neurons are better than those of the traditional. The traditional KNN Cluster and the MKNN Cluster is shown in Figure 6 and Figure7.

TABLE 2 List of winning neurons

kind	number
The first kind	6,12
The second kind	31,32
The third kind	19,20
The fourth kind	1,2,3,7
The fifth kind	16,22,23,24,28,29,34,36

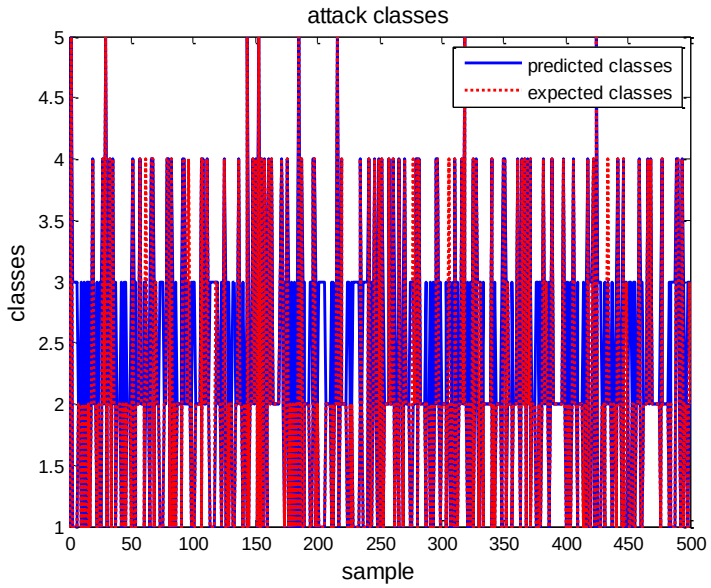

FIGURE 6 The traditional KNN Cluster

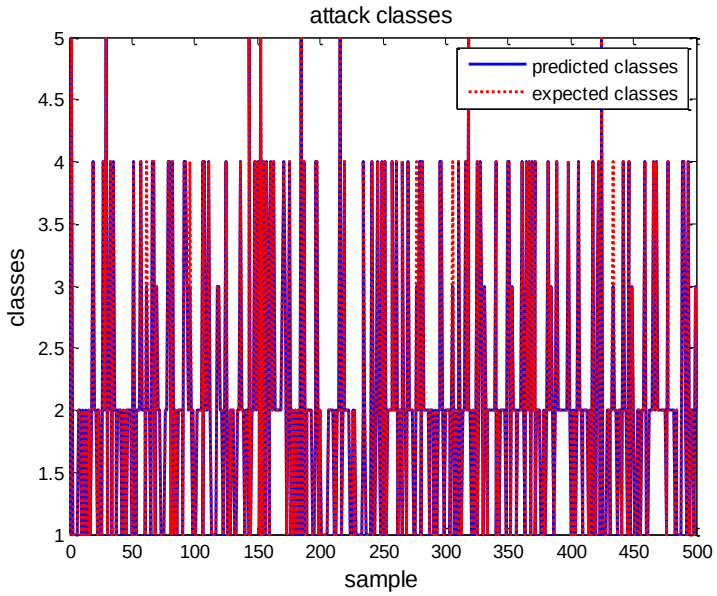

FIGURE 7 The MKNN Cluster

9 Conclusions

Based on the high clarification efficiency of KNN, this essay presents a method of FCM clustering in case of large amount of network invasion data. Typical data is chosen to be trained, which greatly cut down the training time of network classification. Also the introduction of neural neighbourhood function and neural neighbourhood topology identification improves the neural topology distribution and classifies the data more accurately. The result of the simultaneous experiment shows the efficiency of the algorithm in network invasion clustering.

Numerical analysis of sheet metal U-Bending process

Jiansheng Xia*, Shasha Dou

Yancheng Institute of Technology, Yancheng, 224051, China

Nanjing University of Aeronautics & Astronautics, nanjin, 211106, China

Received 16 July 2014, www.cmnt.lv

Abstract

The sheet metal U-bending forming is a complex process, based on the assumption of Prandtl-Reuss flow rule and Von Mises yield criterion, the incremental elastoplastic large deformation finite element model was established based on the Updated Lagrangian Formulation (ULF). The elastoplastic conversions of boundary and deformation are reduced with rmin rule. The friction phenomenon of slippage and viscosity at the boundary interface is revised with increment of revision Coulomb rule. The increment rules are led into the whole stiffness matrix, and derived out the stiffness equation. The studies show that the influence on U-Bending deformation of sheet metal is influenced by die structure and parameter. The results show there is a good consistency between the finite element simulation and experimental result.

Keywords: elastoplastic, FEM simulation, sheet metal, U-Bending, warpage

1 Introduction

Sheet metal forming is a common material processing method, which can be divided into several kinds, such us: stretching, bending, drawing and flanging, etc. Bending is the important forming that pushes sheet mental into a certain shape with different angle and curvature. Bending sheets is commonly used in the area of sheet metal forming, especially in the automotive metal, industrial products and household appliances. The common types of bending are V-Bending, U-Bending and L-Bending [1].

There are some problems in U-Bending, such us thinning, thickening or warping, and unable to obtain the desired shape [2, 3].

In this paper, based on the axisymmetric large deformation elastic-plastic theory to analyse the U-bending of sheet metal, the relationships between the U-Bending quality and parameters are analysed such us: punch die radius, clearance, friction coefficient and plate thickness etc. Finally, the theoretical analysis is verified with the experimental results.

Kim and Thomson [4] found that spring-back and the sidewall curl were proportional to die radius, die clearance, work hardening rate and yield strength after considering the friction factor in U- bending

Lee and Yang [5] analysed U-draw bending process parameters with the finite element method, such us: punch velocity, penalty function, damping ratio, and evaluated the important factor which influencing the spring-back with the taguchi method, and found the element size and arc radius were the significant factor.

Liu [6] analysed U-draw bending spring-back under the variable and fixed plate force with the NUMISHEET93 method, and found the variable power can obtain the better forming quality.

Huang and Chen [2] developed a set of incremental elastic-plastic large deformation finite element program to simulate the V bending spring-back and saddle phenomenon and verified experiment.

Sousa [3] optimized design parameters of V and U bending with the finite element method and Genetic algorithm (GA), those parameters including: punch and die radius, punch displacement and plate force.

2 Experimental Section

2.1 FUNDAMENTAL THEORY

2.1.1 Virtual work principle

It descripts the elastic-plastic deformation with the updated Lagrangian formulation ULF [10], the Virtual work principle formulation can be shown as follows:

$$\int_{V^E}\left(\ddot{\sigma}_{ij}-e\sigma_{ik}\dot{\varepsilon}_{kj}\right)\delta\dot{\varepsilon}_{ij}dV+\int_{V^E}\sigma_{jk}L_{ik}\delta L_{ij}dV=\int_{S_f}\dot{f}\,\delta v_i dS\,, \quad (1)$$

where, $\ddot{\sigma}_{ij}$ is the Cauchy stress tensor, $\dot{\varepsilon}_{kj}$ is the rate of stress tensor, $\dot{\varepsilon}_{ij}$ is the strain tensor, σ_{jk} is the rate of strain tensor, $\delta\dot{\varepsilon}_{ij}$ is the virtual strain tensor of the point, δL_{ij} is the virtual velocity gradient tensor of the point, δv_i is the velocity component, $\dot{f}$ is surface force component, L_{ij} is velocity gradient tensor, V is unit volume, S is unit surface area.

2.1.2 Constitutive relation

In preparing the theory of elasto-plasticity, we have made certain assumptions:

1) The material is homogeneous and isotropic;
2) There is no strain before manufacturing;
3) Temperature effect do not consider when manufacturing;
4) It obeys the laws of the Hooke's Law in elastic stage;
5) It obeys the von Mises yield rule and Prandtl-Reuss plastic flow rule;
6) It contains Isotropic strain hardening in constitutive equation;
7) There are elastic strain stage and plastic strain stage in material strain rate;
8) Punch, die and holder are steel structure;
9) The Bauschinger effect does not consider in reverse unloading.

After assuming above, the constitutive relation can be written as follows:

$$\overset{\circ}{\sigma}_{ij} = C^{ep}_{ijmn}\dot{\varepsilon}_{mn}, \tag{2}$$

$$C^{ep}_{ijmn} = C^{e}_{ijmn} - \frac{C^{e}_{ijkl}C^{e}_{uv}\dfrac{\partial f}{\partial \sigma_{kl}}\dfrac{\partial f}{\partial \sigma_{uv}}}{C^{e}_{kluv}\dfrac{\partial f}{\partial \sigma_{kl}}\dfrac{\partial f}{\partial \sigma_{uv}} + H'\dfrac{\sigma_{uv}\dfrac{\partial f}{\partial \sigma_{uv}}}{\bar{\sigma}}}, \tag{3}$$

where $\overset{\circ}{\sigma}_{ij}$ is Jaumann differential of σ_{ij}, C^{ep}_{ijmn} is the elastic-plastic module, C^{e}_{ijmn} is Elastic module, f is the initial yield function, H' is the strain hardening rate, $\bar{\sigma}$ is Von Mises yield function, the Matrix form of C^{ep}_{ijmn} can be expressed as below:

$$\left[C^{ep}\right] = \left[C^{e}\right] - \frac{1}{S}\begin{bmatrix} S_1^2 & S_1S_2 & S_1S_3 & S_1S_4 & S_1S_5 & S_1S_6 \\ & S_2^2 & S_2S_3 & S_2S_4 & S_2S_5 & S_2S_6 \\ & & S_3^2 & S_3S_4 & S_3S_5 & S_3S_6 \\ & & & S_4^2 & S_4S_5 & S_4S_5 \\ & & & & S_5^2 & S_5S_6 \\ symm & & & & & S_6^2 \end{bmatrix}, \tag{4}$$

where,

$$S = \frac{4}{9}\bar{\sigma}^2H' + S_1\sigma'_{xx} + S_2\sigma'_{yy} + S_3\sigma'_{zz} + 2S_4\sigma'_{yz} + 2S_5\sigma'_{zx} + 2S_6\sigma'_{xy}, \tag{5}$$

$$S_1 = 2G\sigma'_{xx},\ S_2 = 2G\sigma'_{yy}\ S_3 = 2G\sigma'_{zz}, \tag{6}$$

$$S_4 = 2G\sigma'_{yz},\ S_5 = 2G\sigma'_{zx},\ S_6 = 2G\sigma'_{xy}, \tag{7}$$

where σ'_{ij} is deviator of σ_{ij}, G is the friction flow potential, $G = \sigma_1^2 + \sigma_2^2$, $\left[C^{e}\right]$ is the equation in minimum strain, which can be expressed as:

$$\left[C^{e}\right] = \frac{E}{1+\nu}\begin{bmatrix} \frac{1-\nu}{1-2\nu} & \frac{1-\nu}{1-2\nu} & \frac{1-\nu}{1-2\nu} & 0 & 0 & 0 \\ & \frac{1-\nu}{1-2\nu} & \frac{1-\nu}{1-2\nu} & 0 & 0 & 0 \\ & & \frac{1-\nu}{1-2\nu} & 0 & 0 & 0 \\ & & & \frac{1}{2} & 0 & 0 \\ & & & & \frac{1}{2} & 0 \\ symm & & & & & \frac{1}{2} \end{bmatrix}, \tag{8}$$

where E is modulus of elasticity, v is Poisson's ratio. If the material is homogeneous and isotropic, the elastoplastic rate equation can be written:

$$\overset{\circ}{\sigma}_{ij} = \frac{E}{1+\nu}\left[\delta_{ik}\delta_{jl} + \frac{\nu}{1-2\nu}\delta_{ij}\delta_{kl} - \frac{3\alpha\left(\dfrac{E}{1+\nu}\right)\sigma'_{ij}\sigma'_{kl}}{2\bar{\sigma}^2\left(\dfrac{2}{3}H' + \dfrac{E}{1+\nu}\right)}\right]\dot{\varepsilon}_{kl}. \tag{9}$$

If α=1, it is a plastic stage; when α =0, it is a elastic stage or unloading stage.

Equivalent stress and equivalent plastic strain relations can express by *n*-power law equation:

$$\dot{\sigma} = C\left(\varepsilon_0 + \dot{\varepsilon}_p\right)^n, \tag{10}$$

where C is material constant, n is strain hardening index; $\dot{\sigma}$ is the equivalent stress, $\dot{\varepsilon}_p$ is the equivalent plastic strain, ε_0 is the initial strain.

2.1.3 The finite element equation

Finite element analysis is the method that the structure is divided into many small units called discrete entity. Based on Large deformation stress and stress rate relation, the finite deformation of update Lagrangian formulation, material constitution relationship, the velocity distribution of each unit is show below:

$$\{v\} = \leq [N]\{\dot{d}\}, \tag{11}$$

$$\{\dot{\varepsilon}\} = \leq [B]\{\dot{d}\}, \tag{12}$$

$$\{L\} = \leq [M]\{\dot{d}\}, \tag{13}$$

where $[N]$ is shape function, $\{\dot{d}\}$ is nodal velocity, $[B]$ is strain rate-velocity matrix, $[M]$ is velocity gradient-velocity matrix

The principle of virtual work equation and the constitutive equation based on update Lagrangian are linear equation. The formula can be written by the form of incremental representation.

After finite element discretization, the large deformation rigid general equation is written as below:

$$[K]\{\Delta u\}=\{\Delta F\}, \tag{14}$$

where:

$$[K]=\sum_{\langle E\rangle}\int_{V^e}[B]^T\left([C^{ep}]-[Q]\right)[B]dV+\sum_{\langle E\rangle}\int_{V^e}[E]^T[Z][E]dV, \tag{15}$$

$$\{\Delta F\}=\sum_{\langle E\rangle}\int_{S^\varepsilon}[N]^T\{\dot{f}\}dS\Delta t, \tag{16}$$

where $[K]$ is the overall elastoplastic stiffness matrix; $\{\Delta F\}$ is the nodal displacement increment; $\{\Delta u\}$ is the nodal forces incremental; [Q] and [Z] are stress correction matrix.

2.1.4 Friction processing

There is friction in sheet forming process, so we need to pay attention to materials and tools of the interface conditions. When the material moves along the tool surface curve of the slide, the contact force can be expressed as:

$$F=F_l l+F_n n, \tag{17}$$

where F_l is radial force and F_n is normal force, and differential equation of F can be expressed as:

$$\dot{F}=\dot{F}_l l+F_l\dot{l}+\dot{F}_n n+F_n\dot{n}, \tag{18}$$

where differentials of $\dot{l}$ and $\dot{n}$ are expressed as:

$$\dot{l}=-\Delta u_l^{rel}/R, \tag{19}$$

$$\dot{n}=\Delta u_l^{rel}/R, \tag{20}$$

where R is tool radius, Δu_l^{rel} is the local relative velocity between the tool and node, and the nodes relative speed can be expressed as:

$$\Delta u_l^{rel}=\Delta u_l-\dot{u}_{tool}\sin\theta, \tag{21}$$

where Δu_l is the contact tangent displacement increment of nodes, $\dot{u}_{tool}$ is the displacement increment of tooling, θ is the rotation angle.

The increment equation of $\dot{F}$ is expressed as follow:

$$\dot{F}=\left(\dot{F}_l-F_n\Delta u_l/R+F_n\dot{u}_{tool}\sin\theta/R\right)\cdot l+\left(\dot{F}_n-F_l\Delta u_l/R-F_l\dot{u}_{tool}\sin\theta/R\right)\cdot n, \tag{22}$$

Rigid matrix governing equation of the contact nodes is expressed below:

$$\begin{bmatrix}K & \cdots & \cdots\\ \cdots & K_{11}+F_n/R & K_{12}\\ \cdots & K_{21}+F_n/R & K_{22}\end{bmatrix}\cdot\begin{Bmatrix}\cdots\\ \Delta u_l\\ \Delta u_n\end{Bmatrix}=\begin{Bmatrix}\cdots\\ \dot{F}_l+F_n\dot{u}_{tool}\sin\theta/R\\ \dot{F}_l-F_l\dot{u}_{tool}\sin\theta/R\end{Bmatrix}. \tag{23}$$

2.1.5 Incremental steps of R_{min} method

Based on the elastic plastic finite element method with large deformation method, the Yamada r_{min} method [9] is used to judge the function. Each incremental step value is equal to incremental displacement of initial deformation increment of the tooling. Adopted the method of updated Lagrangian formulation, calculated each increment of displacement, strain, stress, load, spring-back value after forming the final shape of sheet mental in unloading condition, the value of load incremental in each step is controlled by $r_{\min}$ method, which is shown as below:

$$r_{\min}=MIN(r_1,r_2,r_3,r_4,r_5), \tag{24}$$

where, r_1 is the maximum allowable strain increment, r_2 is the maximum allowable rotation increment, r_3 is the minimum value in all elastic elements, r_4 is the contact position between free node and tooling, r_5 is the discontent position between free node and tooling.

2.2 NUMERICAL ANALYSIS

2.2.1 *Numerical analysis flow*

Based on the finite deformation theory, ULF equation and $r_{\min}$ method, a set of effective analysis of sheet metal forming process is established. Firstly, a 3D part and mold is designed with the NX software, and then is meshed with NASTRAN software. Secondly, the meshed model is drawn into the data file and did finite element analysis. The simulation flow chart is shown in Figure 1.

Based on the theory upwards, the bending process of U plate type is studied, including relationship between the punch load and displacements, stress and strain, thickness, spring-back and warpage. Some simulation experiments were carried out, of which parameters are friction coefficient (μ), punch radius (r_p), die radius (R_d). The results were verified by the experiment, and optimized and served a reference for U bending designer.

The whole experimental structure is composed of punch, die and blank holder. The experimental model picture was shown as Figure 2 below.

The initial relation of part and die is shown in Figure 2a, also, the punch down a certain stroke is shown Figure

2b. It takes two coordinates to solve the problem, which are fixed coordinates (X, Y, Z) and local coordinates (ξ, η, ζ). based on the right-hand rule, it uses the fixed coordinates (X, Y, Z) when nodes do not contact with the tool, and uses the local coordinates (ξ, η, ζ) when nodes contact with the tool. L-axis is the tangential direction of contact line between the part and tools when n-axis is the normal direction.

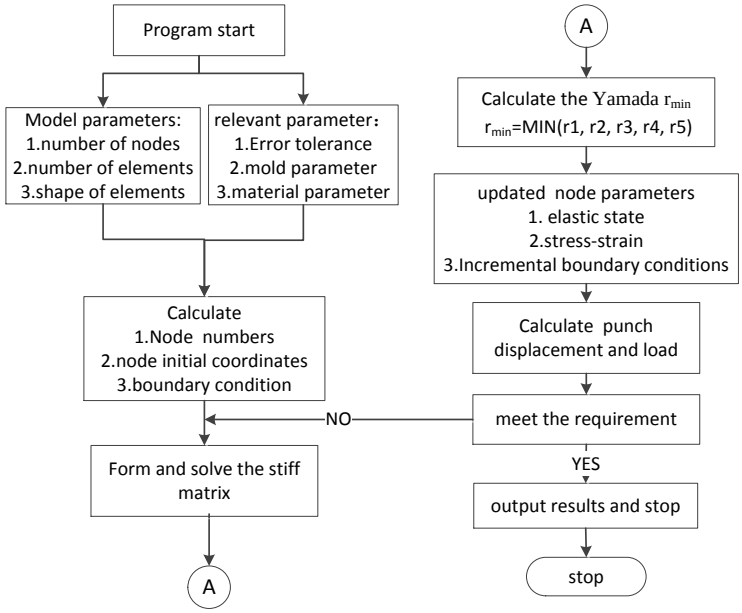

FIGURE 1 Numerical simulation of flow chart

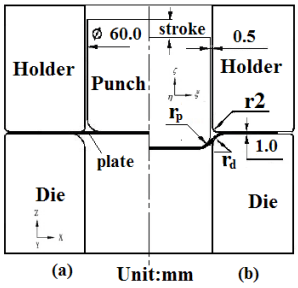

a) before deformation, b) after deformation
FIGURE 2 Sheet metal and die size chart

The contact condition of each node of plates will change which based on deformation in sheet metal forming. When the displacement increment is zero, the boundary conditions of increment displacement of the next node will changes to free node boundary conditions. After checking the contact condition between the part and tool, generalized Rmin method is used. if sheet contacts the mold, the boundary condition will be changed to the contact condition.

Because the structure of sheet model is symmetrical, we take the 1/4 model to analysis.

It uses the quadrilateral segmentation of degenerated shell element in sheet metal meshing, when the die meshing uses the triangle segmentation.

Material parameters for numerical simulation are shown in Table 1 below, the shape of part is rectangular, Length L=120mm, Width W=50mm.

TABLE 1 Material property parameters.

Thickness	T=1mm
Length	L=120mm
Width	W=50mm

Young's modulus	E=210000MPa
Poisson's ratio	ν=0.3
Friction factor	μ=0.14

3 Results and discussion

3.1 STRESS DISTRIBUTION ANALYSIS

As can be seen from the result of simulation in Fig. 3, the initial stress mainly concentrates in fillet of die and punch. When the stroke is 12mm, the mainly stress concentrates in the area of punch fillet, some stress slightly and warpage occurs in bottom. The stress gradually shifted to the side wall plate with the increasing of stroke. When the stroke is 35mm, the sheet detaches the holder, the warping stress eliminates gradually, but the wall tress also exists.

3.2 THICKNESS ANALYSIS

After pressing, there is different stress in U-bending process of the sheet mental. Thickness would be chicken and thinning. In order to study the changes regulation between the thickness and fillet radius of die and punch, four simulation experiments are arranged, such us: r_p=4mm, r_p=8mm, R_d=4mm, R_d=8mm. The thickness of sheet in different position of the X-Axis are measured and recorded in Table 2 below.

TABLE 2 The thickness of sheet in different Relative position-X Axis under different parameters

Parameters	Simulation	Experiment	Simulation	Experiment	Simulation	Experiment	Simulation	Experiment
Relative position – X-Axis(mm)	r_p=4mm		r_p=8mm		R_d=4mm		R_d=8mm	
5	0.799	0.800	0.800	0.800	0.800	0.801	0.800	0.801
10	0.791	0.800	0.798	0.799	0.790	0.798	0.800	0.800
15	0.790	0.799	0.790	0.792	0.790	0.796	0.790	0.798
20	0.781	0788	0.790	0.791	0.781	0.784	0.781	0.786

a) r_p=4mm b) r_p=8mm

c) R_d=4mm d) R_d=8mm

FIGURE 4 Thickness distribution chart under different parameters

As can be seen from the Figure 4, Thickness distribution of sheet can be divided into three regions. The relative positions are from the 0mm to 20mm; the sheet contacts to the punch closely; the thickness is no obvious change. The second area is from the 20mm to 40mm, the sheet is under the axial stress in the area of die fillet, and thin gradually. The third area is from the 40mm to 60mm, the sheet is squeezed into die accompany with punch movement; the sheet flow is hindered, and the thickness increase.

3.3 WARPAGE AND SPRING-BACK ANALYSIS

The reason of warpage in U-Bending is that the sheet which affected by die constraint effect moves along the die side wall, when the punch moves down and sheet slips into the die. The outside edge of sheet is continuous, and reverse force is generated in curve bend, and forces the sheet to deform and warp at bottom of punch.

Measurement method of warpage and springback is shown as Figure 5.

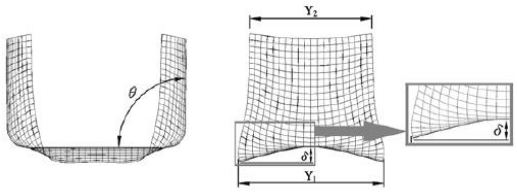

FIGURE 5 Measurement location of warpage and the Springback angle

As can be seen from the Figure 6, the relationship is shown between the relative position and warpage with the different punch stroke. When the stroke is 12.0mm, the warpage is 2.13mm. When the stroke is 16.0mm, the warpage is 3.62mm. When the stroke is 40.0mm, the

warpage is 4.72mm. When unload; the warpage is 4.71mm. The warpage mainly form when the stroke is from 0mm to12.0mm, and it changes slowly outside that scope.

In order to study the change law between warpage and fillet radius of different punch and die, improve the quality of sheet, the simulation experiments, which follow the arrangement below are carried out. Firstly, the punch fillet radius is fixed 6mm, die fillet radius are change from 2mm, 4mm, 6mm, 8mm to 10mm. Secondly, the die fillet radius is fixed 6mm, punch fillet radius are change from 2mm, 4mm, 6mm, 8mm to 10mm. the simulation and experiment results are recorded in Tab3.

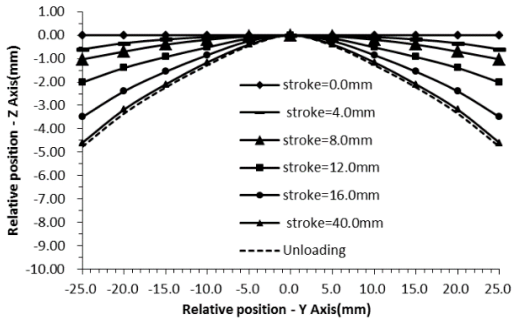

FIGURE.6 The relationship between the relative position and warpage with the different punch stroke

		Exp.	3.85	90.1°	49.65	42.62
10.0		Sim.	3.54	90.6°	49.87	41.32
		Exp.	3.50	90.2°	49.82	41.43

Note: sim.: simulation value, exp.: experiment value, r_p: Punch radius, R_d: Punch radius.
Sheet size: L=120.0mm, W=50.0mm.

As can be seen from the Figure 7, the experimental and simulation results are basically similar. When the punch radius is unchanged, die radius is smaller and warpage is smaller. When the die radius is unchanged, punch radius is smaller but warpage is greater. The best warpage is appear when punch radius r_p=6mm, die radius R_d=2mm, the Min value is 2.67, the changes of Spring-back and width are relatively small.

FIGURE 7 Warpage and spring back angle distribution chart under different parameters

4 Conclusion

Based on the numerical analysis and experimental results, combined with finite element method with the incremental elasto-plastic theory, analysed warpage phenomenon in U-bending process of sheet metal, the following conclusions are obtained as follows.

1) The maximum stress is mainly concentrated in the fillet of punch and die. With the stroke's moving, the stress shifts to the side wall and the distribution is quite uniform.

2) From simulation results it is shown the thinnest of sheet occurs at the fillet of punch, and if rupture, the position will be here. In addition, the end piece of long-axis occurs the thickening.

3) From simulation results it is shown the warpage occurs at tangent of punch and die fillet. Maximum warping appears when the stroke is from 0mm to 12.0mm.When the punch radius is constant, the die radius is smaller, the warpage is smaller too, Figure 7a. When the die radius is constant, the punch radius is greater, but the warpage is smaller, Figure 7b.

For additional experiments analysis, the min warpage can be predicted that when punch radius is 10.0mm, the die radius is 2.0mm, and the warpage can reduce to the minimum 2.52mm. These results are applied to engineering.

Frequency analysis of the area error in the triangular partition of a discrete global grid

Ming Tao*

College of Civil Engineering and Architecture, China Three Gorges University, No.8,Daxue Street, Xiling, District, Yichang, Hubei, China

Received 5 November 2014, www.cmnt.lv

Abstract

The discrete global grid is a method of hierarchical space expression with global scale, multi-resolution, and multi-scale transform features. It is a basic theory related to global geographic information systems and spatial grid computation. The main challenge in the practical application of discrete global grids is the generation of errors. Thus, four typical kinds of global discrete grid models were investigated in this study of partition errors. Area was considered an indicator of partition errors. Furthermore, this study computed the area errors in levels 3 to 10 partitions of each kind of global discrete grid model. The frequency of each indicator was also analysed. Analysis results show that the Synder models have the smallest area deformation.

Keywords: discrete global grid, triangular partition, frequency analysis

1 Introduction

The discrete global grid is a method of hierarchical space expression with global scale, multi-resolution and multi-scale transform features [1]. In this research field, however, errors are a significant problem, especially the deformation of discrete global grid model partitions. This deformation influences the geometrical homogenization of the discrete global grid model [2]. The basic partition deformation problems occur in terms of area, distance, and direction. In this study, the frequency analysis method is employed to investigate the area error in triangular partitions. The partition deformation change rule is analysed by computing the area error and the corresponding frequency characteristics.

2 Study objects

Four kinds of discrete global grid models were selected as the study objects. They represented typical discrete global grid categories.

The QTM model has an octahedral inscribed geometry [3]. Each of the chords between the adjacent nodes of the octahedral is divided into two equal segments. The midpoint of each chord is projected onto the surface of the sphere and becomes a new node. This new node forms a new geometry along with the original nodes in a process called partition, which can be repeated. Each partition is a project process from plane to sphere.

SQT has an icosahedral inscribed geometry [4]. The surface of the sphere is divided into 20 partitions of equal area. Each partition is recursively divided into four spherical triangles of similar area.

The Synder model also has an icosahedral inscribed geometry [5]. The projection transformation equation of this model was developed by Synder in 1992, and its partition method is similar to that of the Fuller model.

STQIE model [6] uses a projection transformation equation based on ERLPR projection. The projection plane is divided into triangles of equal area. The vertices of each triangle are then reversely projected onto the surface of the sphere to form many spherical triangles. These spherical triangles in turn comprise the STQIE grid.

3 Computation method of partition area error

The ideal discrete global grid model is an evenly partitioned unit sphere. Moreover, nodes are uniformly distributed on its surface. The partitions of the ideal model are equal in terms of area and are not afflicted with geometric deformation. Therefore, the ideal model does not display systematic errors. The area values of the ideal model can be regarded as true values. Once determined, the difference between true and calculated values of each discrete global grid model can then be used to analyse the errors.

The area calculation formula of ideal partition is as follows:

$$S_n = 4 \times \frac{\pi}{2^n}, \tag{1}$$

where S_n is the area of a partition in level n and n is the depth of the partition level.

The actual partition area is calculated using the following spherical triangle area formula:

* ***Corresponding author*** e-mail: mingtaomail@163.com

$$S = E \times \pi \times R^2 \times 180^0, \quad (2)$$

where E is spherical excess, and R is spherical radius.

A, *B*, and *C* are set as the three angles of a spherical triangle. Thus, the spherical excess Equation is as follows:

$$E = A + B + C - 180^0. \quad (3)$$

The area error Equation is as follows:

$$S_{\triangle} = E - S_n. \quad (4)$$

In discrete global grids with inscribed geometries, the vertices of the inscribed geometry distribute evenly on the surface of the sphere prior to partition. Thus, the partitions formed by these vertices are equal in terms of area and do not exhibit any errors. These partitions are called level 1 partitions. Level 2 partitions display errors because of the partition algorithms and the systematic error in the model. According to the results of previous research [2], deformation changes in the partitions stabilized after level 10. Thus, the aforementioned grid models are partitioned from levels 3 to 10 in this study to analyse the error change rule.

The area errors in the partitions from levels 3 to 10 are analysed through frequency analysis. This analysis evenly divides the interval between the maximum and the minimum statistical values. Furthermore, the frequency analysis of partition error can reflect whether it is influenced by model systematic error. It can also reflect the influence of subdivision methods on partition deformation.

4 Frequency analysis of partition area error

Figures 1 to 32 present the frequency analyses of the STQIE, SQT, Synder, and QTM models. Each model is divided into partitions ranging from levels 3 to 10.

Figures 1 to 8 depict a single peak shape in the representation of STQIE partition error frequency. The error intervals are both positive and negative. Furthermore, the entire interval is 9.775E-8. The error rate of the negative interval is 53.26%, whereas that of the positive interval is 46.74%.

Figures 9 to 16 also display a single peak shape, but the interval is positive. The entire interval is 3.595E-7, and the error interval of SQT is 3.67 times that of STQIE. Moreover, the distribution of area error in the latter is more concentrated than that in the former. In addition, STQIE has both positive and negative intervals. By contrast, SQT has only a negative interval. Therefore, the area deformation in the STQIE partition is smaller than that in the SQT partition.

The interval of area error frequency in the Synder model is symmetric, and the centre is located at point 0 as shown in Figures 17 to 24. Error distribution is increasingly concentrated in line with the increase in level depth. Furthermore, the partition area is little deformed by systematic error.

Figures 25 to 32 indicate that the frequency representation of the QTM model is irregular in shape. Partition area deformation is greater in this model than in the three other models under the influence of systematic error. Thus, the QTM partition method generates severe area error.

5 Conclusions

A frequency analysis can clearly reflect the characteristics of area error in different grid model types. In particular, the distribution of these errors in the Synder model is symmetrical, and they are mainly induced by the accidental error generated during the computational process. This phenomenon is consistent with the characteristics of equal area projection in this model.

As a result of this projection, the Synder model displays the smallest area error compared with the other three models as per frequency analysis. By contrast, the QTM model exhibits the largest area error among the four models because of its partition method and octahedral inscribed geometry. With respect to area error, the four models are thus ranked in ascending order as follows: Synder, STQIE, SQT, and QTM.

Research on the application of clustering algorithm based on minimum spanning tree

Chen Ye*

College of Science and Technology, Ningbo University, Ningbo City, Zhejiang Province, China, 315212

Received 28 October 2014, www.cmnt.lv

Abstract

Cluster analysis is one of the most important technologies in data mining. Minimum spanning tree (MST) is an advanced algorithm in cluster analysis. Studying MST has important practical significances. Firstly, this paper analysed partitioning, hierarchical, density and grid clustering algorithms based on MST thoroughly. Secondly, implementation principles and shortcomings of these four algorithms were discussed. Finally, practical applications of clustering algorithm based on MST were introduced, aiming to solve some practical problems.

Keywords: data mining, clustering algorithm, MST model

1 Introduction

Nowadays, mature database technology has been developed and data application has been promoted to a new high. People are facing with big data every day. To utilize such big data effectively, researchers developed knowledge discovery in database (KDD) and improve it continuously. Various data mining technologies for different algorithms have been developed [1].

Cluster analysis is an important technology of data mining. However, clustering technology is still developing. Research on cluster analysis not only has theoretical significance, but also can widen its practical applications. Figure 1 shows the whole process of cluster analysis.

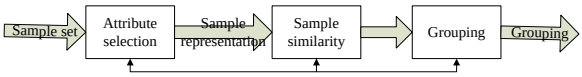

FIGURE 1 Process of cluster analysis

As things of one kind come together, researchers divide data objects into different groups according to their attributes. This is known as cluster analysis (Figure 2)

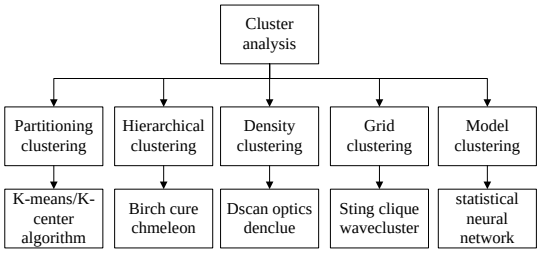

FIGURE 2 Cluster analysis

To overcome shortcomings of classical clustering analysis algorithms, a clustering algorithm based on MST was developed. It is an advanced cluster analysis and can eliminate blindness of clustering analysis significantly. With the continuous development and improvement of MST, four clustering algorithms based on MST have been developed: partitioning clustering algorithm based on MST, hierarchical clustering algorithm based on MST, density clustering algorithm based on MST and grid clustering algorithm based on MST [2] (Figure 3).

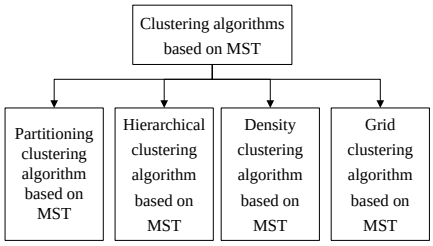

FIGURE 3 Classification of clustering algorithms based on MST

2 Classification of clustering algorithms based on MST

2.1 PARTITIONING CLUSTERING ALGORITHN BASED ON MST

Principle: in the partitioning clustering algorithm based on MST, features of dataset *D* are analysed and its complete undirected graph with weight (*G*) is constructed firstly. Secondly, researchers will divide the MST (*T*) into *k* subtrees according to the characteristics of *G*. So an initial cluster valued *k* is gained. When dividing the *T*, there's a common practice: longest *k*-1 sides in *T* will be found and deleted, so that the distance sum of sides in all subtrees will be the smallest and *k* initial clusters are acquired. This is based on the principle that different points can be grouped into different clusters according to different side lengths. In *D*, distance between sides of different clusters is longer than distance between points within the same cluster.

* ***Corresponding author*** e-mail: yechen@nbu.edu.cn

Therefore, we will get a globally optimal solution. Finally, *k* clusters can be generated by k-means clustering and adjusting affiliation of data objects in different clusters.

Steps of partitioning clustering algorithm based on MST are:

Step 1: Users construct the complete undirected graph with weight (*G*) of the clustering dataset (*D*) according to its characteristics.

Step 2: Users build the MST (*T*) of *G* by using appropriate algorithm.

Step 3: Users set parameters and divide *T* into *k* subtrees according to a specific criterion. *k* initial clusters and the initial cluster centre are generated.

Step 4: Users adjust the cluster centre continuously until get the desired one.

To sum up, partitioning clustering algorithm based on MST has significantly higher accuracy than other classical ones. This is contributed by its scientific and practical generation of initial cluster. Instead of random choose, it generates *k* initial clusters according to the principle of MST. Although the partitioning clustering algorithm based on MST has higher scientific and practical value than traditional ones, it still has some shortcomings for its intrinsic properties:

1) Low generation efficiency of *T*. The time complexity of *T* generation is the function of n^2: $0(n^2)$.

2) Low flexibility. When dividing the *T*, we have to delete the longest *k* sides. This is impractical for many datasets with different geometric distributions. In Step 3, the actual geometric distribution of dataset shall maintain close to the initial cluster in order to get good clustering effect. However, we have to set some parameters and use different division rules. Therefore, improvement is needed to make improved MST satisfy actual cluster distribution [3].

2.2 HIERARCHICAL CLUTERING ALGORITHM BASED ON MST

Analysis: Users build MSTs of the clustering dataset. Later, they cluster data objects using different hierarchical processes according to some characteristics of these MSTs.

Principle: Hierarchical clustering algorithm is an important algorithm. It is composed of agglomeration and splitting. Hierarchical clustering that decomposes from bottom to up is called as agglomeration. In agglomeration, each object is viewed as an independent class. Then, features of these objects will be analysed and similar classes will be combined. It ends until classes are combined into one class. Hierarchical clustering that decomposes from upper to bottom is known as splitting. It concentrates all data objects together as a class. Later, these data objects will be iterated continuously to split the class into smaller classes. It ends until each small class contains only one data object. Both agglomeration and splitting enable users to set different end conditions according to desired classes. Distance between classes is an important reference index to agglomeration and splitting. Common measurements of distance between classes are listed:

Minimum distance:

$$d_{\min}(c_i - c_j) = \min_{p \in c_i, p' \in c_j} \left| p - p' \right|. \quad (1)$$

Maximum distance:

$$d_{\max}(c_i - c_j) = \max_{p \in c_i, p' \in c_j} \left| p - p' \right|. \quad (2)$$

Mean distance:

$$d_{mean}(c_i - c_j) = \min_{p \in c_i, p' \in c_j} \left| m_i - m_j \right|. \quad (3)$$

Average distance:

$$d_{avg}(C_i, C_j) = \frac{1}{n_i n_j} \sum_{p \in C_i} \sum_{p' \in C_j} \left| p - p' \right|. \quad (4)$$

In hierarchical clustering algorithm based on MST, users build MSTs according to different features of the clustering dataset, which then will be put in proper orders. Subsequently, proper combination objective function is selected to judge whether two adjacent sides shall be combined. To ensure the accuracy, all sides are judged. Finally, several sides are combined gradually until get the appropriate clustering result.

Although it has been improved a lot compared to classical hierarchical clustering algorithms, it still has some shortcomings:

1) Low efficiency. Since the time-consuming Prim or Kruskal algorithm is the main algorithm used to build MST, the time complexity of hierarchical clustering algorithm based on MST is the function of n^2: $0(n^2)$. It is almost inapplicable to clustering of big dataset.

2) Great fluctuation of clustering results. It often uses appropriate objective function for side combination, which requires users to set many experimental parameters. As a result, different users with different experiences will come to significantly different clustering results [4].

2.3 DENSITY CLUSTERING ALGORITHM BASED ON MST

In many division approaches, users often groups objects according to their distances. This often ends with a ball cluster. To get different shaped clusters, researchers developed a clustering algorithm based on density. In density clustering algorithm, users preset a threshold. If density of adjacent areas is higher than the threshold, data points will be clustered continuously. In other words, given a class, there must be data points higher or equal to a numerical value in the analysing area. Density clustering algorithm can process "noise" data and get clusters of different shapes. However, it has low efficiency. Its time complexity is generally a function of n^2: $0(n^2)$. Moreover, it performs unsatisfying to dataset with uneven density [5].

Since parameter setting in DBSCAN algorithm is very

complicated, Ankerst proposed the OPTICS (Ordering Points to Identify the Clustering Structure) algorithm based on the ordering of classes. It shows good performances to dataset with uneven density. In China, Zhao Yanchang et al. developed an isodense clustering algorithm. In most clustering algorithms based on density, parameter setting affects clustering structure directly and causes violent fluctuation of clustering results.

Analysis: Firstly, users build the MST of given dataset. Secondly, users divide the MST into many subtrees in view of its characteristics. Thirdly, these subtrees will be clustered according to densities of these subtrees, getting corresponding clustering structure.

Principle: Firstly, users analyse feature of given dataset and build the MST. Secondly, they find out the longest $k-1$ sides in the MST and delete them to get an initial cluster valued *k*. The MST after division can be expressed by $T[k]$. Viewed from the space perspective of dataset, the dataset is divided into *k* local areas. Data objects with similar density are divided into the same area. Thirdly, an appropriate function is selected to calculate the function value of each initial cluster. The core object (*d*) of $T[k]$ is determined. All objects within the direct density of d will be clustered. Now, the density clustering result based on MST is acquired.

Such improved density clustering algorithm is significantly superior to the classical ones. However, it still has some shortcomings because of its intrinsic properties.

1) Low efficiency. Since the time-consuming Prim or Kruskal algorithm is the main algorithm used to build MST, the time complexity of density clustering algorithm based on MST is the function of n^2: $0(n^2)$. Its application to clustering of big dataset is restricted.

2) Great fluctuation of clustering results. Users have to set parameters of $T[k]$ when judging objects within the direct density of d. These parameters often have no fixed reference standard and shall be set according to users' experiences. As a result, different users with different experiences will come to significantly different clustering results.

2.4 GRID CLUSTERING ALGORITHM BASED ON MST

Grid clustering algorithm is to develop a network structure by quantize an object space into limited units. It is advantageous for quick operation, but disadvantageous for low clustering accuracy.

To further accelerate the operation of grid clustering algorithm, Wang et al. put forward grid-based multiresolution clustering algorithm. It is quick in operation and has higher data processing efficiency. Moreover, it can make real-time data processing upon data adding and updating in the dataset and produce new clustering result. Though it has evident advantages, it is inferior in clustering accuracy.

Schikuta E. proposed two improved grid clustering algorithms which achieves outstanding performances in clustering of big dataset. These grid clustering algorithms are superior for no consideration to data input sequence, low requirement on data distribution and flexible data dimension and size, but inferior for low clustering accuracy [6].

Analysis: Firstly, users divide the dataset space into many basic grids and then distribute data objects to different grids. Based on users' density threshold, density of grids will be calculated and served as the basis for clustering. Secondly, users can build the MST of dense grids through appropriate algorithm and get *k* clusters by deleting longest *k*-1sides.

Although grid clustering algorithm based on MST has obvious advantages than other classical ones, it is inferior for fluctuating clustering results. As the basis of grid clustering algorithm based on MST, dense grid often needs various parameters to build the MST. Since these parameters often have no fixed reference standard, different users will set different parameters, thus getting different dense grid structures. As a result, they will build different MSTs and finally achieve different clustering results [7].

3 Application of clustering algorithms

Cluster analysis plays an important role in our daily lives. Clustering algorithms, an important mean of cluster analysis, are widely used. For example, they are often used in pattern recognition, research of market prospect, image processing, document classification, etc. [8].

In market analysis, cluster analysis is useful when marketers want to implement different marketing strategies to different customer groups. It can divide customers into groups according to purchase mode and make corresponding marketing strategies to win high market acceptance of their products. Cluster analysis is also highly appreciated in urban planning. It helps analysers and designers to divide and design the region into different types of residential area [9]. In seismic study, researchers can make a cluster analysis on geological faults and divide existing seismic centre into different clusters, so that analysers can get a comprehensive understanding on the distribution of seismic belt. In biological field, cluster analysis on genes of animals and plants enables scientists to classify genes with similar functions and discover deeper information. In real estate sales, salesmen can make different marketing strategies according to the cluster analysis of different commercial residential building [10].

The application of cluster analysis based on MST in genetic noise reduction is introduced. Figure 4 is the model of collected genetic data points, in which there are six noises. Noises in the model were processed using a clustering algorithm based on MST under different *k* and *q*. Results are listed in Table 1. When $k=3$ and $q=2$ or 3, the cluster analysis based on MST achieved the best noise reduction effect.

To verify reasonability of parameter settings, a proof test was conducted. DNA data were acquired using probing tools and 7 elements of the probe data interface $(a_0, a_1, a_2, a_3, a_4, a_5, a_6)$ were collected. Subsequently, the rotation matrix R Equation (5) and the displacement matrix Equation (6) were used to process data. Genetic data points simulated according to Equation (7) are drawn onto a coordinate system. Finally, noises of data points were reduced under the optimal k and q. The test results find good accordance with the cluster analysis.

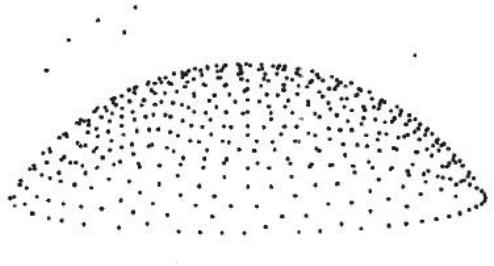

FIGURE 4 Model of genetic data points

$$R = \begin{vmatrix} a_0^2 + a_1^2 - a_2^2 - a_3^2 & 2(a_1a_2 - a_0a_3) & 2(a_1a_3 + a_0a_3) \\ 2(a_1a_2 + a_0a_3) & a_0^2 + a_2^2 - a_1^2 - a_3^2 & 2(a_2a_3 - a_0a_1) \\ 2(a_1a_3 - a_0a_2) & 2(a_2a_3 + a_0a_1) & a_0^2 + a_3^2 - a_1^2 - a_2^2 \end{vmatrix}, \quad (5)$$

4 Conclusions

This paper analyses four clustering algorithms based on MST: partitioning clustering algorithm based on MST, hierarchical clustering algorithm based on MST, density clustering algorithm based on MST and grid clustering algorithm based on MST. Principles, shortcomings and applications of these four clustering algorithms are introduced.

Routing method of quantum genetic algorithm

Jing Yang*

Baotou Vocational & Technical College, Baotou, Inner Mongolia, 014035, China

Received 1 May 2014, www.cmnt.lv

Abstract

Quantum genetic algorithm was applied in the work to solve multiple-QoS routing problems of bandwidth-delay constraint, thus meeting current requirements for multimedia messaging. Mathematical model and constraint condition of QoS routing were established, analysing algorithms principles and steps that how quantum genetic algorithm optimized QoS routing. By comparing average fitness and maximum polymerization fitness under different running times, quantum genetic algorithm can effectively find optimal solutions to multiple-QoS routing problem.

Keywords: genetic algorithm, quantum genetic algorithm, mathematical model, route choice, fitness

1 Introduction

Quantum genetic algorithm is a probability evolutionary algorithm with combination of quantum computing and genetic algorithm. State vector expression of quantum was introduced to genetic code, using quantum logic gates for chromosomal evolution, achieving better results than genetic algorithm. Therefore, there are important theoretical and practical values in solving practical problems with quantum genetic algorithm. QoS routing involves multi-objective optimization problems, thus the selection of appropriate algorithm has critical influence on the control of network bandwidth, delay and cost [1-3].

2 Quantum genetic algorithm

2.1 QUANTUM BIT ENCODING

A two-state quantum system, acted as an information storage unit in quantum computer, was called quantum bit. Quantum bit or qubit is the smallest information unit in quantum computing. A quantum bit has three states, namely $|0>$ state, $|1>$ state, and superposition state between $|0>$ and $|1>$. Therefore, the state of any quantum bits can be described as [4]:

$$|\varphi>=\alpha|0>\beta|1>,$$

where α, β are called probability amplitude of corresponding state of quantum bits, satisfying the normalization condition:

$$|\alpha|^2+|\beta|^2=1.$$

2.2 QUANTUM GATE RENEWAL

As the executing agency of evolution operations, quantum gates are selected according to specific issues. Quantum Rotating Gate was chosen in the work, with the following adjusted operation:

$$U(\theta_i)=\begin{bmatrix}\cos(\theta_i) & -\sin(\theta_i)\\ \sin(\theta_i) & \cos(\theta_i)\end{bmatrix}. \quad (1)$$

Renewal process is as follows:

$$\begin{bmatrix}\alpha_i'\\ \beta_i'\end{bmatrix}=U(\theta_i)\begin{bmatrix}\alpha_i\\ \beta_i\end{bmatrix}=\begin{bmatrix}\cos(\theta_i) & -\sin(\theta_i)\\ \sin(\theta_i) & \cos(\theta_i)\end{bmatrix}\begin{bmatrix}\alpha_i\\ \beta_i\end{bmatrix}. \quad (2)$$

From Equation (2) we can obtain:

$$\begin{cases}\alpha_i'=\alpha_i\cos(\theta_i)-\beta_i\sin(\theta_i)\\ \beta_i'=\alpha_i\sin(\theta_i)+\beta_i\cos(\theta_i)\end{cases}. \quad (3)$$

Therefore,

$$|\alpha_i'|^2+|\beta_i'|^2=[\alpha_i\cos(\theta_i)-\beta_i\sin(\theta_i)]^2+[\alpha_i\sin(\theta_i)+\beta_i\cos(\theta_i)]^2=|\alpha_i|^2+|\beta_i|^2=1. \quad (4)$$

Then it can be transformed as:

$$|\alpha_i'|^2+|\beta_i'|^2=1. \quad (5)$$

3 Qos routing problem

Currently, Internet network mostly adopts *best – effort* routing protocol with the shortest-path routing strategy, thus the requirements cannot be satisfied for receiving and transmitting multimedia information. From network users' perspective, QoS (Quality of Service) routing algorithm should firstly meet users' QoS request, namely finding a

***Corresponding author** e-mail: yangjing8825@126.com

transmission path corresponding to various conditions from source node to destination node. From facilitators' perspective, the use of network resources can be optimized through QoS routing algorithm [5, 6].

Users' Qos is decided by various parameters of network. QoS defined by RFC2216 refers to packet transmission characteristics described through parameters of bandwidth, delay, delay jitter and packet loss rate. Only by meeting users' requirements of QoS parameters can network reach the required services quality of network.

Typically, the topology and link state information of network can be abstracted as a weighted graph $G(V,E)$ in Figure 1 [7]:

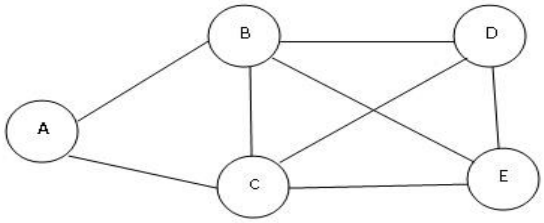

FIGURE 1 Network topology diagram of QoS routing

Vertices in Figure 1 represented network nodes; edges referred to network links; $V=(V_1,V_2,...,V_n)$ was the set of all switching nodes of router; $E=(E_1,E_2,...,E_n)$ indicated the link set connecting routers. QoS routing selection was to find the route satisfying requirements of network QoS from Figure 1.

4 QoS routing based on quantum genetic algorithm

4.1 MATHEMATICAL MODEL OF QOS ROUTING

A mathematical model of QoS routing should be established for better analysis and solutions of problems. A,B,C,D,E in Figure 1 represented the routes, while ligatures between two routes were pathways of routes. Each link was expressed with cost, width and delay, respectively.

Based on above analysis, issues of cost, bandwidth and delay are key factors affecting QoS routing. Not all factors should be considered in design of specific routing algorithm, because too complex algorithm will affect actual application of algorithm. Therefore, appropriate algorithms should be designed for different practical needs, dealing with different constraints [8-10].

For any links, (a,b) and $D(a,b)$ expressed the delay of link generation; $B(a,b)$ represented available bandwidth of the link; $C(a,b)$ was the cost of communication process.

Assuming the delay of path between u,v is:

$$delay(u,v)=\sum_{(a,b)\in P(a,b)} D(a,b)\,. \tag{6}$$

Available bandwidth of $P(u,v)$ is:

$$width(u,v)=\min_{(a,b)\in P(u,v)} B(a,b)\,. \tag{7}$$

The cost of $P(u,v)$ in communication process is:

$$\cos t(u,v)=\sum_{(a,b)\in P(a,b)} C(a,b)\,. \tag{8}$$

The mathematical model of QoS routing can be implied from Equations (6), (7) and (8), as well as constraint condition of QoS routing. The mathematical model is as follows:

Objective function:

$$\cos t(T)=\min(\sum_{(a,b)\in Er} C(a,b))\,. \tag{9}$$

Constraint condition:

$$\begin{aligned}&\forall v\in M,\ \sum_{(a,b)\in P_T(u,v)} D(a,b)\le D_{\max}\\ &\forall v\in M, Width(P_T(s,v))\ge W_{\min}\end{aligned}\,. \tag{10}$$

4.2 ALGORITHM FLOW OF QOS ROUTING BASED ON QUANTUM GENETIC ALGORITHM

Based on principles of quantum genetic algorithm and the mathematical model of QoS routing, algorithm flow of the work is as follows:

1) Initialize population $Q(t_0)$, and randomly generate n chromosomes encoded with quantum bits;

2) Measure each individual of the initial population $Q(t_0)$ to obtain corresponding definite solutions;

3) Evaluate the fitness of each definite solution;

Fitness function:

$$\cos t(T)=\min(\sum_{(a,b)\in Er} C(a,b))\,. \tag{11}$$

In the Equation, $C(a,b)$ represented the required cost of passing links in communication process. The smaller of fitness function value, the lower of communication cost.

4) Record optimal individual and corresponding fitness;

x_i was the i-th place of current chromosome; $best_i$ the i-th place of optimal chromosome; $f(x)$ fitness function; $s(\alpha_i,\beta_i)$ rotation angle direction; $\Delta\theta_i$ rotation angle size.

The calculated fitness $f(x)$ was compared with $f(best_i)$ - the fitness of current optimal individual in its population $f(best_i)$. If $f(x)>f(best_i)$, then the corresponding quantum bits should be adjusted, making probability amplitude (α_i,β_i) evolve toward the direction conductive to emergence of x_i. If $f(x)>f(best_i)$, then

probability amplitude (α_i, β_i) should evolve toward the direction conductive to emergence of $f(best_i)$.

5) Determine whether the calculation process can be completed: exit if the end conditions were met, or continue calculation;

6) Measure each individual of population $Q(t)$, and obtain corresponding definite solutions;

7) Evaluate the fitness of each definite solution;

8) Adjust individuals with quantum revolving gat $U(t)$, and obtain new population $Q(t+1)$;

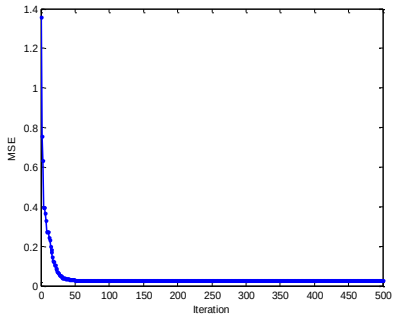
9) Record optimal individual and corresponding fitness;

10) Return to Step 5) with iterations $t = t+1$.

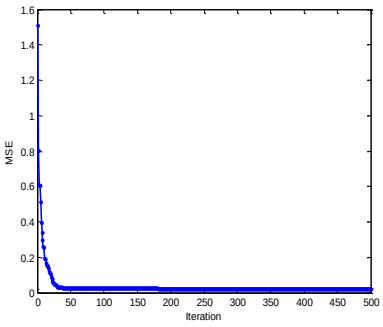
5 Simulation analysis

In order to verify the validity and effectiveness of the algorithm, corresponding parameters should be set as follows. Maximum genetic algebra: 500; population size: 40; maximum delay constraints: $D_m = 10$; minimum bandwidth constraints: $W_m = 100$; crossover probability: $p_c = 0.3$; mutation probability $p_m = 0.15$; passed path: $num\,\mathrm{var} = 8$.

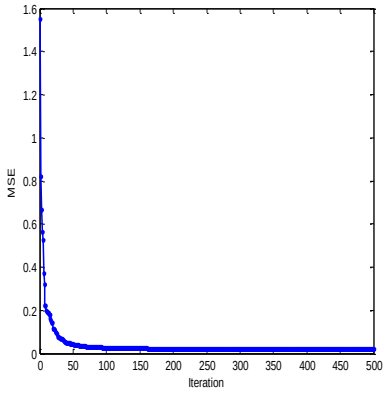
Convergent graph of different running times was shown in Figure 2:



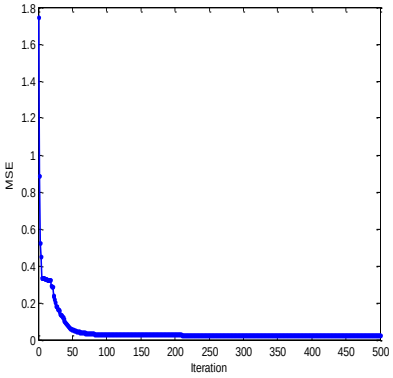
a) 1 running time



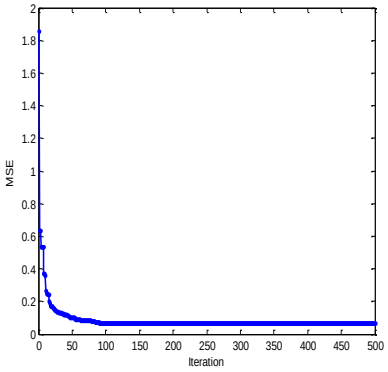
b) 5 running times



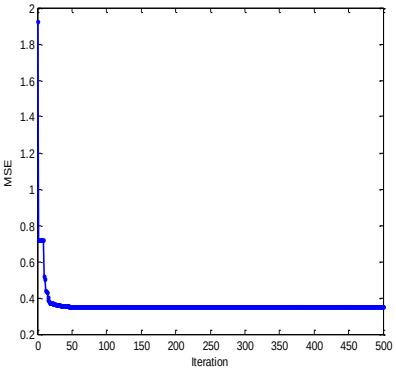
a) 10 running times



b) 20 running times



a) 25 running times



b) 50 running times

FIGURE 2 Convergent graph of different running time

Simulation results were shown in Table 1:

TABLE 1 Optimization results of fitness function

Running times	Average fitness	Maximum polymerization fitness
1	11.2616	0.1848
5	10.7399	0.1872
10	10.5234	0.1895
20	10.1735	0.1935
25	9.6875	0.1957
50	9.3012	0.1984

Table 1 showed that average fitness value presented a decreasing trend with increase of running times. The required cost of individuals continued decreasing, while maximum polymerization fitness value showed an increasing trend with increase of running times. This indicated that individuals' fitness more and more adapted to required conditions of specific issues. Meanwhile, better results could be obtained through running times of quantum genetic algorithm.

6 Conclusions

In the work, quantum genetic algorithm—integrating principles of quantum computing with genetic algorithm—was applied to QoS routing. Objective function and constraint condition were determined by constructing a mathematical model of QoS routing. Then, simulation solving was conducted in accordance with the principles and steps of the algorithm in the work. Simulation results showed that individual required cost presented a decline trend with increase of running times; individual fitness showed a rising trend with the increased of running times. Therefore, better results can be obtained with multiple running times of quantum genetic algorithm.

A novel method for K-Means clustering algorithm

Jinguo Zhao*

School of Computer and Information Science, Hunan Institute of Technology, Hunan, 421002, China

Received 1 March 2014, www.cmnt.lv

Abstract

This paper investigated K-means algorithm, a well-known clustering algorithm. K-means clustering algorithms have some shortfalls and defects, and one defect is reviewed in this study. One of the disadvantages of K-means clustering algorithms is that they can produce clusters that do not always include all the correct components. It is due to the presence of the error rate during the clustering process. The purpose of this research was to decrease error rates in the K-means clustering algorithm and to reduce iteration of running this algorithm. A novel method is proposed to calculate the distance between cluster members and cluster centre. To evaluate the algorithm proposed in this study, seven well-known data sets consisting of Balance, Blood, Breast, Glass, Iris, Pima and Wine data sets were used. This investigation revealed that the performance of K-means algorithms was increased and resulted in valid clusters and that it reduced error rates, run time and iteration.

Keywords: K-means, clustering algorithm, error rate, iteration, reduction, stable

Introduction

Clustering is an important technique used in many fields such as knowledge discovery and information retrieval. It helps researchers find related information more quickly [33]. As a result, researchers are kept up to date with new findings in their fields. Clustering is the process of grouping or dividing a set of objects into subsets (called clusters) so that the objects that are similar to one another are placed within the same cluster and dissimilar objects are placed in other clusters [26]. In other words, an object is similar to at least one other object in the same cluster and dissimilar to objects in other clusters in terms of predefined distance or similarity measure [31]. Currently, clustering as a tool for classification, pattern analysis, information extraction and decision making, has attracted the tendency of numerous investigators. Numerous techniques and approaches have been introduced in the literature. Each of these methods includes a certain measure, and has its own disadvantages and advantages. In general, there is no comprehensive technique and measure for optimal clustering of any kind of data [6].

In this study, a new understanding of the clustering algorithm was expressed. The most prominent, the most commonly used and the most popular clustering algorithm is the K-means algorithm, and it is used in this study. Among clustering algorithms, the K-means clustering algorithm can be used in many fields, including image and audio data compression, pre-process system modelling with radial basis function networks and task decomposition of heterogeneous neural network structure. One problem of clustering algorithms is that the clustering results are not always stable. In repeating the clustering algorithm several times, correct answers may be found in some trials but in others it may not find the correct answers due to instability. The clustering algorithm should be constant and stable, which is reviewed in this survey. This problem and gap as mentioned in the fourth part are related to the summary of a section of a Jain article [23].

Cormack (1971) first proposed that clusters should be internally integrative and externally segregated, suggesting a certain degree of uniformity within clusters and heterogeneity between clusters. So, many investigators tried to operationalize this description by minimizing within-group disparity [11, 14, 15, 45]. Following these efforts at maximizing within-group uniformity, Sebestyen (1962) and MacQueen (1967) separately developed the K-means technique as a strategy that tries to discover optimal partitions. Based on this significant advancement, K-means has become very popular, earning a place in a variety of textbooks on multivariate techniques [28, 32, 46], cluster analysis [17], pattern recognition [12], statistical learning [19, 43]. There are many surveys in K-means clustering algorithm field, yet this algorithm has still not been completely improved. In this paper, we reduced the error rate of the clustering algorithm and increased the stability of this algorithm.

K-means clustering algorithm has a number of disadvantages and problems, and one problem was reviewed in this study. This paper is organized as follows. Section 2 and 3 review the literature about clustering algorithms and K-means clustering algorithm. Section 3 describes the proposed method and research methodology used in this study. Section 5 explains the experiment conducted as a part of this study in the K-means clustering algorithm and improved K-means clustering algorithm, and the results are evaluated in Section 6. Finally, conclusions are drawn and discussed in Section 7.

2 Related works

In this section, the brief literature of the clustering algorithms is examined in which different researchers have previously expressed and improved these algorithms. Forgy's technique [16] randomly allocates each point to one of the K clusters homogeneously. The centres are then given with the centroids of these primary clusters. This technique has not basis of theoretical as, for example, random clusters have not homogeneity of internal [2]. Jancey's technique [25] allocates to each centre a combinatorial point randomly generated within the space of data. However, as the data set fills the space, a number of these centres may be too distant from any of the points [2], which might lead to the formation of unfilled clusters [13].

MacQueen (1967) suggested two different techniques. The first technique is the default choice in the Quick Cluster method of IBM SPSS Statistics [38], which obtains the first K points in X as the centres. An obvious disadvantage of this technique is its sensitivity into data ordering. The second technique selects the centres randomly from the data points. The foundation behind this technique is that random choice is likely to result in the selection of points from dense regions, points are suitable applicants to be centres. Ball and Hall's technique [5] obtains the centre of X, as the first centre. It then crosses the points in optional order and obtains a point as a centre if it is at least T units apart from the formerly selected centres until K centres are taken. The aim of the distance threshold T is to make sure that the seed points are well parted. The Simple Cluster Seeking technique [47] is the same as Ball and Hall's technique with the distinction that the first point in X is obtained as the first centre. This technique is applied in the FASTCLUS method of SAS [13, 22].

Maximin technique [30] selects the first centre c1 randomly and the i-th (i{2,3,...,K}) centre ci is selected to be the point that has the most minimum distance to the formerly chosen centres, that is c1,c2,...,ci-1. This technique was originally expanded as an approximation to the K-centre clustering problem. It should be referred that, motivated with a vector quantization request, Katsavounidis et al.'s variant [30] obtains the point with the greatest Euclidean standard as the first centre.

Al-Daoud's density technique [1] first regularly partitions the data space into M decomposed hyper-cubes. It then randomly chooses K Nm/N points as of hypercube m (m {1,2,…,M}) to take a total of K centres where Nm is the points number in hypercube m. Bradley and Fayyad's technique [7] begins by randomly partitioning the data set into J subsets. These subsets are clustered by k-means initialized through MacQueen's second technique producing J sets of intermediate centres, each with K points. These centre sets are united into a superset that is then clustered through k-means J times, each time initialized by a diverse centre set. Members of the centre set that give the least SSE are then taken as the final centres. Pizzuti [40] advanced Al-Daoud's density-based technique using a solution grid method. This technique begins through 2D hypercube and iteratively divides these as the number of points they accept increases. The k-means++ technique [3] interpolates between maximin technique and MacQueen's second technique. It selects the first centre randomly and the i-th (i{2,3,...,K}) centre is selected to be x, where md(x) denotes the distance of minimum from a point x to the previously chosen centres.

The PCA-Part technique [44] applies a divisive hierarchical system based on PCA (Principal Component Analysis). In this method, starting from a first cluster that contains the all data set, the technique iteratively chooses the cluster with the greatest SSE and divides it into two sub-clusters by a hyper-plane that it passes with the centre of cluster and is orthogonal to the way of the basic eigenvector of the covariance matrix. This method is repeated until K clusters are taken. The centres are then given through the centres of these clusters. Lu et al.'s technique [35] applies a two phase pyramidal method. The attributes of each point are first encoded as integers. These points of integer are considered to be at stage 0 of the pyramid. In the phase of bottom-up, starting from stage 0, adjacent data points at stage k (k{0,1,...}) are averaged to take weighted points at stage k+1 until at least 20 K points are taken. Onoda technique [39] first computes K Independent Components (ICs) [21] of X and then selects the i-th (i{1,2,...,K}) centre as the point that has the least cosine distance [13].

3 K-means clustering algorithm

The aim of data clustering, also known as cluster analysis, is to discover the normal grouping of a set of points, objects or patterns. The Merriam-Webster dictionary defines cluster analysis as ‘‘a statistical classification method for discovering whether the individuals of a population fall into different groups by making quantitative comparisons of multiple characteristics.” The goal is to develop a clustering algorithm that will find the normal groupings in the data of unlabelled objects [23]. Cluster analysis or clustering is a method of assigning a set of data objects into clusters where all the objects in a cluster are considered to be similar based on common features. Clustering is an unsupervised learning-based technique for statistical data analysis used in many fields including data mining, pattern recognition, image analysis, and bioinformatics [8]. Selecting clusters of optimally is an NP-hard problem [48]. Clustering algorithms include many algorithms, and K-means algorithm is the most popular. -means algorithm is a rather simple but well-known algorithm for grouping objects [29]. This algorithm is so well known and has widely applied that researchers consider it the equivalent of clustering algorithms.

The term "K-Means" was first used by James MacQueen in 1967, though the idea originates with Hugo Steinhaus in 1956. A standard algorithm was first proposed by Stuart Lloyd in 1957 as a technique for pulse-

code modulation, though it was not published until 1982. The classical K-means clustering algorithm aims to detect a set C of K clusters Cj with cluster mean cj to reduce the sum of squared errors. Number of clustering C is a very important parameter [20].

The K-means algorithm is a greedy algorithm, which can only converge to a local minimum, even though recent study has exposed the enormous possibility that K-means could converge to the overall optimum when clusters are well detached [27,37]. K-means begins with a primary partition with K clusters and allocates patterns to clusters so as to decrease the squared error.

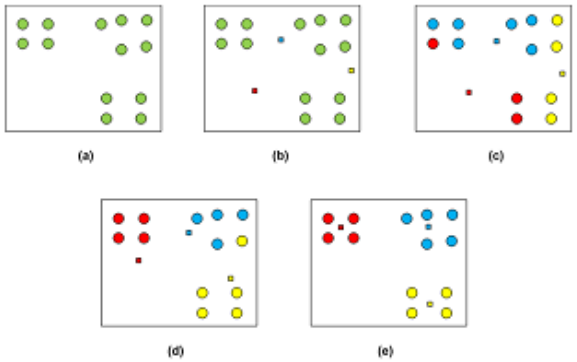

FIGURE 1 K-means clustering algorithm for 3 clusters

The Figure 1 expresses an illustration of the standard K-means algorithm on a dataset of two-dimensional with three clusters. Figure 1, sets out a design for a K-means clustering algorithm. (a) Two-dimensional input data with three clusters; (b) three seed points chosen as cluster centres and initial assignment of the data points to clusters; (c) & (d) intermediate iterations updating cluster label and the centres; (e) final clustering obtained by K-means clustering algorithm at convergence [23]. Clustering algorithms have many applications, but there are problems with this algorithm. One problem is that the clustering algorithm and K-mean algorithm are not always constant. The clustering algorithm may generate correct answers several times in some trials but in some other trials it may not find the correct answers due to instability. In order for the clustering algorithm to stabilize, it must reduce the number of errors and the number of iteration steps in the algorithm. Therefore, the proposed method tries to reduce the error rate and iteration in the K-means algorithm.

4 The proposed method

In the method used in this study, numbers were taken from outside of the cluster centre. Data sets were added and the K-means clustering algorithm was implemented. In this study is calculated the distance in the clustering algorithm to determine the best method. When the data distance was calculated correctly, cluster errors in the algorithm were reduced. The principal goal of the research methodology used in this study was error reduction in the K-means algorithm. In this section, the initialization of the proposed method is first checked. Then, the improved K-means clustering algorithm is expressed. Last, the problem formulation and proportion is expressed.

4.1 INITIALIZING THE CENTRE

In this study, initial value is randomly selected, after the data set was applied as cluster centres are selected randomly in the initial stage. All members of the dataset attributes must be an integer. A set of datasets was generated using MATLAB for testing the effect of various parameters and size of the problem on the time taken through the algorithm. By selecting the required number of cluster centres randomly in the domain [1, number of rows], which chosen randomly is a normal distribution. First, the dataset is applied to MATLAB. If the dataset format is more usable in MATLAB, it must be converted to the format used. Text format for the datasets have been used in this study. Second, the number of rows in the dataset is determined and then the number of clusters is selected as random numbers from 1 to the number of rows. For example, if the number of clusters is three and number of rows in the dataset is 150, three random numbers from 1 to 150 will be selected. So, selected attributes of these rows are initial cluster centres.

4.2 PROPOSED ALGORITHM

In the proposed algorithm (Reduction of Error Rates in K-Means algorithm or RER-K-Means algorithm), equation is used to calculate the distance between the members of dataset and cluster centres. Another difference between RER-K-means algorithm and K-means algorithm is that comparing and finding the minimum distance used a better method, which it is described more in the next section. Actually, equation is a compatibility function that would calculate and minimize the intra cluster distance. The equation has K clusters of N data vectors classified according to the distance from each cluster centre; it is located at one of the clusters. In this equation, the total aggregate of Euclidean distance of all the data vectors from cluster centres that they own is calculated and added to each other.

Therefore, by determining the optimal, centres can easily be clustered and the answer is that one that is best clustered. Using the equation, the number of clustering errors is reduced and it is close to being stable. It follows that the main objective of this equation is to ensure that minimum distances between the centres of the clusters are optimized, till, K-means clustering algorithm is to be improved. This study calculated the distance between the centre of the cluster and the cluster members using one of the best ways to calculate distance, which is the Euclidean function in MATLAB. Also, calculations of the distance between centres of the cluster and the cluster members are eliminated as additional unnecessary operations have a negative impact on the calculation. Accordingly, the proposed algorithm will be clustered; cluster members will

be assigned to data sets, reducing the error rate and stabilizing clustering algorithms.

4.3 PROBLEM FORMULATION

The RER-K-means clustering algorithm is further described in this section. The programming code was written using MATLAB software. A coding program was used to reduce the complexity of the algorithm, and the best method for clustering data was calculated in the K-mean algorithm. In the following algorithm, the RER-K-means clustering algorithm that was implemented in MATLAB is shown. In algorithm 2, the RER-K-means clustering algorithm is described, which the Euclidean method was used to calculate the distance between clusters. The RER-K-means clustering algorithm (Reduction of Error Rates in K-means clustering algorithm) has eleven stages, which are described below.

Step 1: At first, the target dataset is applied to the MATLAB software. The dataset must have the clustering conditions.

Step 2: In this step, the number of rows of the dataset is found followed by selecting desired numbers of rows randomly as cluster centres. The selected attributes of the random rows are assumed to be initial cluster centres.

Step 3: Specifying the number of iterations, it is considered 50 steps for all datasets in this study. All main processes were placed into this loop. This is known as the named outer loop.

Step 4: A loop is created for the first to the last dataset in which all the main instructions can be placed. This loop is the inter loop.

Step 5: At this stage, the distances of cluster centres which have been previously considered from all members of the dataset are calculated. To calculate the distance, the coordinates of the cluster centre in one array and attributes of a row as dataset in another array are placed, and then the distance between these two arrays is calculated using the following formula. This operation is carried out for all cluster centres in one step.

Step 6: In this step, the distances of all cluster centres from one of the datasets are calculated separately and the minimum distance is taken into consideration. Now, members of datasets are placed in the cluster with the minimum distance.

Step 7: In this step, some variables are defined to represent summation of distances between cluster centre and its members. The number of define variables should be equal to the number of clusters. For instance, if there are 3 clusters, three variables s1, s2 and s3 are defined in which si is summation of distances among ith cluster centre to its member. (i=1,2,3).

Step 8: This step is the end of inter loop. It means that steps 4 to 7 are run until the ending condition of inter loop.

Step 9: Variable S which is intra cluster distance is defined as summation of s1, s2, s3and so on. From converging of S it is deducted that algorithm has stabilized. Generally, S should be tried to minimized as far as possible.

Step 10: The means of any cluster should be determined separately. Then, at the end of any step, the determined means are considered as cluster centres for the next step.

Step 11: This step is the end of outer loop. It means steps 3 to 8 are run until the ending condition of outer loop.

4.4 THE FORMULA

The steps shown in section 4.3 were used to calculate the error rate. It was required to calculate two measures; the number of error patterns and the total number of patterns, which was used to find the error rate in the improved K-means clustering algorithm and the K-means clustering algorithm in all data sets of this study. In next section, it will be seen that the RER-K-means algorithm reduced the error rate and iteration. In this algorithm, additional operations that have a negative effect on the calculation must be avoided. In all the data sets, the K-means clustering and the RER-K-means algorithms implementation were similar and only the data set name and data set coordinates were changed by the algorithms.

5 Experimental results

The clustering results are compared with K-means and improved K-means algorithm. These are implemented with the number of clusters as equal to the number of classes. Meanwhile, the number of data sets selected to solve the problem in the next section can be fully expressed. To check the results, two important criterions are used to error rates and iteration of running.

5.1 DATA SET

Experiments have been performed on seven data sets which consist of Balance, Blood, Breast, Glass, Iris, Pima and Wine that were selected from standard data set UCI. Each of them is described in the following:

Balance Scales (Balance): Balance Scale data set is composed of 625 instances, 4 attributes and 3 classes. Each example is classified as having the balance scale tip to the right, tip to the left, or balanced. Balance dataset contains 46.08% of class L, 7.84% of class B and 46.08% of class R.

Blood Transfusion Service Centre (Blood): This data set adopted the donor database of Blood Transfusion Service Centre in Hsin-Chu City in Taiwan. Blood data set has 748 samples which are 748 donors selected at random from the donor database. This data set has 5 attributes which include R (Recency - months since last donation), F (Frequency - total number of donations), M (Monetary - total blood donated in c.c.), T (Time - months since first donation), and a binary variable representing whether donor donated blood in March 2007 (1 stand for donating blood; 0 stands for not donating blood). The dataset contained 76% no (0) and 24% yes (1). Breast Cancer Wisconsin, Original (Breast): The Breast Cancer

Wisconsin dataset has 699 instances of cytological analysis of fine needle aspiration of breast tumors. In this data set each instance contains 10 attributes that are computed from a digitized image of a fine needle aspiration of a breast mass. Attributes of this data set include radius, texture, perimeter, area, smoothness, compactness, concavity, concave points, symmetry, and fractal dimension. The dataset contains 241 (34.48%) malignant instances and 458 (65.52%) benign instances [18].

Glass Identification (Glass): This data set has 214 samples and seven classes. Every sample in this data set has 10 attributes. Seven kinds of glass are in the data sets including building windows float, building windows non-float, vehicle windows float, vehicle windows non-float, containers, tableware and headlamps.

Iris: This data set is based on Iris flowers recognition with three different classes each consisting of 50 samples. Every sample has four attributes. It presents 150 instances containing width and length measures of the sepals and petals of three species of the flower Iris: 'Setosa', 'Versicolor' and 'Virginical'. With 4 attributes and 3 classes, each containing 50 objects, the aim is to cluster similar species based on their measurements [18, 49].

Pima: This data set is allocated to recognize diabetic patients. A total of 768 samples are classified into two groups consisting of 500 and 268 samples, respectively. Every sample in this data set has 8 attributes [49].

Wine: The Wine dataset has 178 instances and 13 attributes, which correspond to the results of chemical analyses performed with three types of wines produced in the same region of Italy, but from different cultivations. Attributes include alcohol content, acidity, alkalinity, color intensity, among others. The dataset has 59 instances of the first class, 71 instances of the second class and 48 instances of the third [18]. The databases used were obtained from the UCI data warehouse [4].

The relevant datasets are implemented in the clustering algorithm and proposed algorithm and compared in depth. In this study, two measures are used to compare the names of the error rates and number of iterations. In the next section, these two measures will be discussed above data sets.

5.2 RESULTS OF ERROR RATE

In this section, results concerning the number of errors of the proposed K-means clustering algorithm on the data sets are reviewed. In the previous section, it was noted that in this study, seven data sets have been selected to analyse the proposed K-means algorithm. These data sets are standard and are selected from UCI data sets. The proposed K-means algorithm is applied to the respective data sets to determine the results; the number of errors and the graphs and charts can then be fully expressed. In this study, our main objective is to improve the K-means clustering algorithms. To verify the improved algorithm, the improved clustering algorithm will be tested on the some data sets to answer the question of whether this algorithm is improved or not. Thus, the seven data sets (Balance, Blood, Breast, Glass, Iris, Pima and Wine) are implemented separately in the MATLAB software of the proposed algorithm and the results are discussed in this study. In Figure 2, clustering of seven clusters in Glass data set with improved K-means clustering algorithm is displayed. This data set has seven regular clusters, indicating that the clusters are not merged.

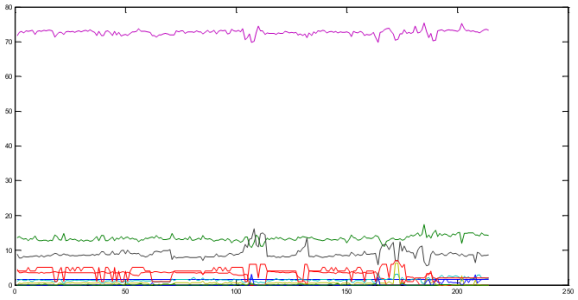

FIGURE 2 Display clustering the Glass data set with improved K-means algorithm

The proposed K-means algorithm was first applied to the Balance dataset. The specifications of this data set are described in the previous section, but will be mentioned briefly here. The Balance data set has 625 instances and 3 classes. In the MATLAB software, code programming proposed K-means algorithm is implemented and Balance data set is loaded.

Secondly, the proposed K-means algorithm was applied to the Blood dataset. The specifications of this data set are described in the previous section, but will be mentioned here briefly. The Blood data set has 748 instances and 2 classes. In the MATLAB software, code programming proposed K-means algorithm is implemented and Blood data set is loaded. The scattering diagram shows improved K-means clustering algorithm on the Blood data set. This diagram indicates the 748 members and the distance among members in this data set. In the diagram it is shown that a small number of members are scattered, mostly in the one level. In this data set are two clusters that are not regular. This means that the first and second clusters are merged; the Blood data set is such that the first and second clusters are not completely separated. In Figure 3, clustering of three clusters in Iris data set with improved K-means clustering algorithm is displayed. This data set has three clusters (first cluster, the first to fifty members; second cluster, members fifty one to one hundred; third cluster, members one hundred one to one hundred fifty). It can be seen that, in the first cluster, there are no errors after clustering, which means an error rate for the first cluster of zero. In the second cluster, there is a small error rate, but in the third cluster, the error rate is higher than both previous clusters. In general, the graphs display the clustering in the Iris data set using improved K-mean clustering algorithm.

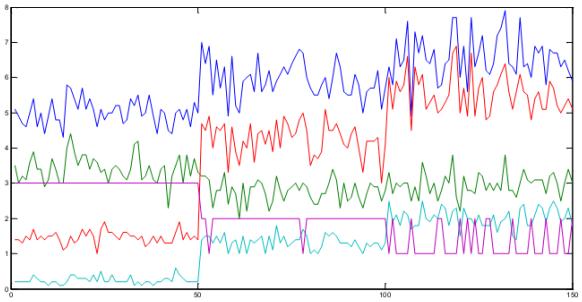

FIGURE 3 Display clustering the Iris data set with improved K-means algorithm

The proposed K-means algorithm was applied to the Breast dataset. The specifications of this dataset are described in the previous section but will, however, be mentioned briefly here. The Breast data set has 699 instances and 2 classes. In the MATLAB software, code programming the proposed K-means algorithm is implemented and Breast data set is loaded. The scattering diagram is shows an improved K-means clustering algorithm on the Breast data set. This diagram indicates the 699 members and the distance among members in this data set. Two clusters of Breast data set clustered with improved K-means clustering algorithm are displayed. In this data set are two clusters that are not regular. This indicates that the first and second clusters are merged; the Breast data set is such that the first and second clusters are not separated. Each algorithm was run twenty times and each time, the algorithm was repeated 50 times to achieve stability. In general, the algorithm is executed 1000 times for each data set. Five factors (number of true, number of errors, intra cluster distance, iteration and error rate) are compared to the improved K-means clustering algorithm and K-means clustering algorithm on the Breast data set. In all factors, the proposed algorithm is much better than previous algorithms.

5.3 EVALUATION OF RESULT

In this section the results of the experiments conducted in section 4 are compared to the results of the improved K-means clustering algorithm and the K-means clustering algorithm. One important factor for the clustering algorithm is intra cluster distance that will be reviewed first. For better comparison, both algorithms are run 20 times on all data sets. All diagrams that can be seen in the intra cluster distance of the proposed clustering algorithm have been improved and in all cases the intra cluster distance is reduced. Also, the intra cluster distance is constant during program execution, indicating the algorithm is stable. It can be seen that the proposed algorithm 20 times the intra cluster distance, meaning that the algorithm is stable. One of the main problems in the K-means clustering algorithm is stability, which the proposed algorithm has almost solved.

In this section, the results of the experiments obtained in section 4 are discussed and evaluated. The results were discussed with the three criteria, intra cluster distance (average), intra cluster distance (standard deviation) and error rate (average) for seven data sets. In the three comparison criteria between the improved K-means clustering algorithms and K-means clustering algorithm it can be seen that the improved K-means clustering algorithm is the best in each case. In general, the proposed algorithm reduces the error rate and intra cluster distance, and it will lead the clustering algorithm to become stable.

6 Conclusions

This paper focuses on a disadvantage of the K-means clustering algorithm, which is that the clustering algorithm has a high error rate. It also referred to one of the main problems in the K-means algorithm which is that the K-means clustering algorithm is not always stable. In this study, an algorithm was proposed to solve this problem in order to reduce the error rate in K-means clustering algorithms and to stabilize the algorithm. In this paper, examining the improved K-means clustering algorithm with the K-means clustering algorithm involved the consideration of five factors (average, standard deviation, best and worst) and four criteria (numbers of true, numbers of errors, intra-cluster distance, iterations and error rate). For comparing the improved K-means algorithm and K-means algorithm seven data sets were used (Balance, Blood, Breast, Glass, Iris, Pima and Wine) and the proposed algorithm shows better performance in all these data sets. In summary, the proposed algorithm has better efficiency than the K-means clustering algorithm in the all measures used in this study, the intra cluster distance and error rate was reduced in the proposed algorithm and the improved algorithm is closer to being stable. In this study a method is proposed to solve one of the main problems of K-means clustering algorithm, which is that the algorithm is not always consistent. In this survey, one of the best ways to calculate the distance it to use the Euclidean distance calculation in the MATLAB software to calculate the members distance from the cluster centre. Also, it should be noted that when calculating the Euclidean distance, additional operations that have a negative effect on the calculation must be avoided. Thus, the purpose of this paper is to improve the calculation of the members distance from the centre of the cluster, which this will help to stabilize algorithm clustering and reduce the error rate. Future work related to this paper can be done as a continuation as other problems of clustering algorithms can be studied using these data sets. Also, the proposed algorithm in this paper can be examined on other data sets and clustering algorithms and the obtained results compared. Finally, other criteria can be studied with the proposed algorithm on the new data set and data sets in this article.

Abstract

Transition priorities might be a useful mechanism when modelling using Petri nets. Accordingly, the newest CPN Tools, widely used for modelling and simulating the Coloured Petri net, implements transition priorities. Whereas, the algorithms compute enabling for all transitions in a highest-priority-first order. In the real system, it is usually that there are priorities relationships not for all transitions but only some ones. Based on the above analysis, this paper put all the transitions, having priority relations, into one group and advances relative theoretical definitions of transition priorities in group, such as absolute preset of transition, key place set, key colour set, etc. Furthermore, it proposes new algorithms when the systems have different key place set and key colour set, and construct the model of the interrupt priorities to solve the problem of software model checking for interrupt system.

Keywords: Petri net, CPN, transitions, transition priorities in group, counter place

1 Introduction

In the process of development of Petri network, in order to better describe realistic system, researchers advanced various high-level Petri net models, such as: time Petri nets [1,2], Stochastic Petri nets [3,4], Colored Petri nets [5,6], Priorities Petri nets [7], Hybrid Petri nets [8], and so on. These extended concepts enhanced Petri net description of capabilities, furthermore, modelling various Petri net had been widely applied in the synchronous system, asynchronous system, simulation [9, 10] and analysis [11, 12] process. However, the actual applications need a better tool to simulate and verity generated models. CPN Tools widen the usage of Petri nets in practical work [13-15].

CPN Tools version 4.0 [16], supporting transition priorities, could specify priority P_HIGH, P_NORMAL or P_LOW [17] for transitions, and could also directly give an integer. Nevertheless, this kind of priorities is static and absolute priority for all transitions, precedence relations, in the actual system, exist among not all transitions but some of them.

Reference [18] proposed to increase one Anti-Place to address the transition priorities, shown in FIGURE 1. The Anti-Place is effective, only if the place had tokens in initial state, however, most systems could not meet the mentioned requirements. Reference [19] used the concept of generalized complement position (Place), changing Petri net system with dynamic priority into the Petri net system with non-priority, but the algorithm was too complex even for constructing a simple system.

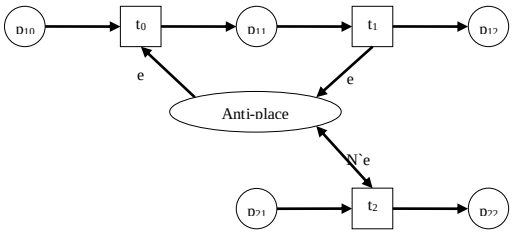

FIGURE 1 Anti-place for transitions with priorities

The remainder of this paper is structured as follows: in the next section, it presented background material and in Section III it provides the definitions of transition priorities in group, key place set and key colour set, etc., and In Section IV, it presents algorithms for increasing one "counter place" to calculate the change of tokens in key place set. Furthermore, the next section, the article solve the practical work interrupt relational model by using the above definitions and algorithms. In Section VI, it concludes and provides directions for future works.

2 Petry net and coloured Petri net

2.1. PETRI NET (PLACE/TRANSITION NET OR P/T NET).

A Petri net is one of several mathematical modelling languages for the description of concurrent systems. A Petri net is a directed bipartite graph, in which the nodes represent transitions and places. The directed arcs described which places are pre- and/or post- conditions, for which transitions (signified by arrows).

***Corresponding author** e-mail: neiep_wh@163.com

A Petri net is a 5-triple $PN=(P,T,F,W,M_0)$ [20], where:

(i) $P=\{p_1,p_2,p_3,...,p_n\}$ is a finite set of places.

(ii) $T=\{t_1,t_2,t_3,...,t_n\}$ is a finite set of transitions.

(iii) $F\subseteq(P\times T)\cup(T\times P)$ is a set of arcs (flow relation).

(iv) $W:F\to\{1,2,3,...\}$ is a weight initial marking.

(v) $M_0:P\to\{1,2,3,...\}$ is the initial marking.

$P\cap T=\Phi$ and $P\cup T\neq\Phi$.

The **preset** of a transition or place x is the set of its input places or transition: ${}^\bullet x=\{y\mid(y,x)\in A\}$; its **postset** is the set of its output places or transition: $x^\bullet=\{y\mid(x,y)\in A\}$.

The **preset** of a set $X_1(X1\subseteq P\vee X_1\subseteq T)$ is the set of its input sets, ${}^\bullet X_1=\bigcup_{x\in X_1}{}^\bullet x$; its **postset** is the set of its output sets $X_1^\bullet=\bigcup_{x\in X_1}x^\bullet$.

However, basic Petri nets have limitations. One of the limitations is 'homogenous' tokens: the tokens inside place represent resources; then in Petri nets, all these resources are of the same type and cannot be differentiated. Another limitation of Petri net is that it is not possible to impose additional logical functions ('firing conditions') for a transition.

2.2 COLOURED PETRI NETS (CP-NETS OR CPN)

Coloured Petri nets is one of popular extensions of basic Petri net. In a standard Petri net, tokens are indistinguishable. Nevertheless, in a Coloured Petri Net, each token has a value, which could be descripted with colour set.

A CP-net is a 9-tuple $CPN=(\Sigma,P,T,A,N,C,G,E,I)$ [21], where:

(i) Σ is a finite set of non-empty types, also called colour sets;

(ii) P is a finite set of places;

(iii) T is a finite set of transitions;

(iv) A is a finite set of arcs such that:

$P\cap T=P\cap N=T\cap A=\Phi$;

(v) N is a node function. It is defined from A into $P\times T\cup T\times P$;

(vi) C is a colour function. It is defined from P into E;

(vii) G is a guard function. It is defined from T into expressions such that:

$\forall t\in T:[Type(G(t))=Boolean\wedge Type(Var(G(t)))\subseteq\Sigma]$.

(viii) E is an arc expression function. It is defined from A into expressions such that:

$\forall a\in A:[Type(E(a))=C(p)_{MS}\wedge Type(Var(E(a)))\subseteq\Sigma]$,

where p is the place of $N(a)$;

(ix) I is an initialisation function. It is defined from P into closed expressions.

Such that:

$\forall p\in P:[Type(I(p))=C(p)_{MS}]$.

In popular tools for Coloured Petri nets, such as CPN Tools, the values of tokens are typed, and could be tested (using guard functions) and manipulated with a functional programming language.

3 Definitions of transitions priorities in group

In order to solve transitions priorities in group, the relative definitions listed as follows.

3.1. $P_S(t)$ (TRANSITION PRIORITIES IN GROUP)

When one transition t is enabled, there is another transition t_k, $(t_k\neq t)$ could also be enabled, but they have different priorities. A group set is composed of all transitions, which could be enabled at the same time and have different priorities. The group set $S=\{t,t_k\}$, the transition propriety of t in group set S is called $P_s(t)$. Similarly, the transition propriety of t_k in group set S is $P_s(t_k)$.

3.2 T_p (GROUP OF TRANSITIONS WITH PRIORITIES)

When multiple transitions could be enabled at the same time, there is relationship of priorities among transitions in the group. The group is an ordered collection of the sort, according to the priorities from high to low. Defined as follows:

A CP-net with Transitions priorities is a 10-tuple $CPN^*=(\Sigma,P,T,A,N,C,G,E,I,S)$, where:

S *is* a finite set of group of enabled transitions with priorities. For each, $T_p\in S$,

(i) $T_p\subseteq T, and\mid T_p\mid>1$;

(ii) $\forall t_i,t_j\in T_p,(j>i)$, transition t_i and t_j could be enabled at the same time, and have different priorities. The priorities of t_i in group T_p is $P_{T_p}(t_i)$, and t_j is

$P_{T_p}(t_j),\ P_{T_p}(t_i)\geq P_{T_p}(t_j)$;

(iii) In group of transitions with priorities $T_p=\{t_1,t_2,t_3,...\}$, at least one t_i, making $P_{T_p}(t_i)>P_{T_p}(t_{i+1})$.

3.3 $[{}^{\bullet}t_i]$ (ABSOLUTE PRESET OF TRANSITION t_i)

Absolute preset of transition t_i is composed of the places, which are elements of preset of t_i, but not be preset of other transitions in the same group T_p.

$$[{}^{\bullet}t_i] = \{p \mid p \in {}^{\bullet}t_i \wedge (\forall t_k \in T_p (k \neq i), p \notin {}^{\bullet}t_k)\}. \quad (1)$$

3.4 P_k (KEY PLACE SET)

P_k (Key Place Set) is a set of places, effecting transition priorities in same group. Search algorithm of P_k as follows:

STEP 1: Identify Group of Transitions with Priorities T_p.

STEP 2: Find Key Place Set P_k according to the following Equation:

$$P_k = \{\bigcup_{i=1}^{n} {}^{\bullet}t_i - \bigcap_{i=1}^{n} {}^{\bullet}t_i \mid t_i \in T_p\} - [{}^{\bullet}t_n]. \quad (2)$$

Firstly, identify preset for each transition t_i, $(t_i \in T_p)$ in group T_p, then, removed public preset of them. Finally, expurgated the absolute preset of transition t_n (with the lowest priority in group T_p).

3.5 $C_k(p)$ (KEY COLOUR SET OF KEY PLACE P) AND $C_k(P_k)$ (KEY COLOUR SET OF KEY PLACE SET P_k)

$C_k(p)$ (Key Colour Set of Key Place p, for short Key Colour Set) is a multi-set of colour set of key place $p(p \in P_k)$. They effected the change of tokens in the key klace p.

Usually, if the key place p has simple colours set $C(p)$, the key colour set of p is same with $C(p)$. Otherwise, p has compound colour set, the key colour set is a multi-set, composed with elements in compound colour set.

$C_k(P_k)$ (Key Colour Set of Key Place Set P_k) is a multi-set of key colour set for each key place p in group P_k.

$$C_k(P_k) = \sum_{k=1}^{n} C_k(p). \quad (3)$$

Supposing that:

(i) The key place set is $P_k = \{p_1, p_2\}$.

(ii) The colour set of p_1, a simple colour set, is $C(p_1) = c_1$, and the key colour set of p_1 is $C_k(p_1) = c_1$. Length of $C_k(p_1)$ is $|C_k(p_1)| = 1$.

(iii) The colour set of p_2, a compound colour set $C(p_2) = c_1 \cdot c_2 \cdot c_3$, and the key colour set of p_2 is $C_k(p_2) = \{c_1, c_2\}$. Length of $C_k(p_2)$ is $|C_k(p_2)| = 2$.

Then, $C_k(P_k) = \{c_1, c_1, c_2\}$ is a multi-set, and the length of $C_k(P_k)$ is $|C_k(P_k)| = 3$.

3.6 ${}^{\bullet}\overline{p}$ (RELATIVE PRESET OF P) AND $\overline{p}^{\bullet}$ (RELATIVE POSTSET OF P)

p is a key place. The relative preset and postset of p must be set of transitions.

$$ {}^{\bullet}\overline{p} = \{t \mid t \in {}^{\bullet}p \wedge (Type(E(a_{in})) \cap C_k(p) \neq \Phi)\}, \quad a_{in} = (t, p) \in A \quad (4)$$

$$ \overline{p}^{\bullet} = \{t \mid t \in p^{\bullet} \wedge (Type(E(a_{out})) \cap C_k(p) \neq \Phi)\}, \quad a_{out} = (p, t) \in A \quad (5)$$

4 Algorithms of transitions priorities in group

4.1 ALGORITHM 1: MODEL FOR $|P_k| = 1$ AND $|C_k(P_k)| = 1$

Example 1: FIGURE 2 is a typical of concurrent systems with priority relationships. When t_1 and t_2 are enabled at the same time, t_1 has a higher priority. However, when t_{10} and t_1 are enabled simultaneously, they have no priorities, randomly trigger.

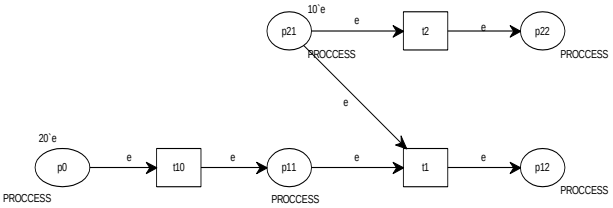

FIGURE 2 Source Model,with $|P_k| = 1$ and $|C_k(P_k)| = 1$

STEP 1: Identify group of transitions with priorities T_p.

In Figure 2, transition set is $T = \{t_1, t_2, t_{10}\}$. t_1 and t_2 have priorities between them, but have no priorities with other transitions. Furthermore, the priority of t_1 is higher than t_2. The group of enabled transitions with priorities is T_p, $T_p = \{t_1, t_2\}$ and $P_{T_p}(t_1) > P_{T_p}(t_2)$.

STEP 2: Identify P_k, the key place set of T_p, and $C_k(P_k)$, the key colour set of P_k.

$\bullet t_1 = \{p_{11}, p_{21}\}$,

$\bullet t_2 = \{p_{21}\}$,

$So, P_k = \{\bigcup_{i=1}^{2} \bullet t_i - \bigcap_{i=1}^{2} \bullet t_i \mid t_i \in T_p\} - [\bullet t_2] = \{p_{11}\}$,

$C_k(p_{11}) = \{PROCCESS\}$,

$C_k(P_k) = \{PROCCESS\}$.

STEP 3: Modify the CPN model, increasing one "counter place" to calculate tokens in key place set.

STEP 3.1: Increase variable for "counter place".

var n:INT;

STEP 3.2: Increase "counter place" for key place set $P_k = \{p_{11}\}$ in CP-net model, with definition of colour set and initial value.

Increase "counter place" *count*, with colorset *INT*. Because the initial count of the key colour PROCCESS is 0, the initial value of "counter place" *count* is 0.

STEP 3.3: If the relative preset of the key place p is not empty, added two arcs from "counter place" *count* to $\bullet\overline{p}$; and if the relative postset of the key place p is not empty, add two arcs from "counter place" *count* to $\overline{p}\bullet$. Added arcs describe the change of tokens in key place.

Transition t_{10} triggered, place p_{11}. Increase one *PROCCESS*, while t_1 triggered, place p_{11} decreased one *PROCCESS*. So, added two arcs from *count* to its relative preset $\bullet\overline{p_{11}} = \{t_{10}\}$, one is outcoming arc with function "n", the other is incoming arc with function "n+1". Similarly, added two arcs from *count* to its relative postset $\overline{p_{11}}\bullet = \{t_1\}$, one is outcoming arc with function "n", the other is incoming arc with function "n-1".

STEP 3.4: added one bi-directional arc with function "0", from "counter place" *count* to other transitions with lower priorities in the same group.

For $T_p = \{t_1, t_2\}$ in the model, extracted one bi-directional arc from *count* to t_2.

The finished model is shown in Figure 3.

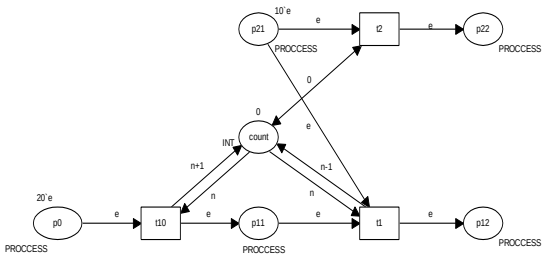

FIGURE 3 Model with priorities $|P_k| = 1$ and $|C_k(P_k)| = 1$

4.2 ALGORITHM 2: MODEL FOR $|P_k| \geq 1$ AND $|C_k(P_k)| > 1$

Example 2: Added two nodes, p_{21} and t_{20}, in FIGURE 2. Transition t_1 could enable, only when p_{11}, p_{21} and p_{31} have tokens in place. Furthermore, t_1 has a higher priority than t_3. However, t_1 and t_3 couldn't plunder privilege of other transitions, t_1 should have same priority with t_{10} and t_{20}, as shown in FIGURE 4.

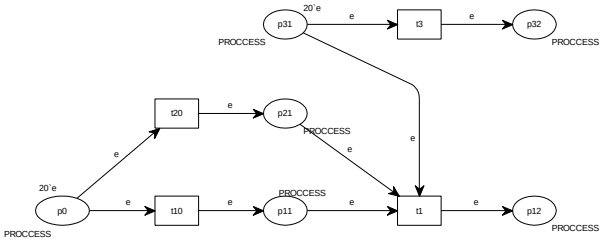

FIGURE 4 Source Model with $|P_k| \geq 1$ and $|C_k(P_k)| > 1$

STEP 1: Identify group of transitions with priorities T_p.

In Example 2, transition set is $T = \{t_1, t_3, t_{10}, t_{20}\}$. The priority of t_1 is higher than t_3. The group of transitions with priorities is T_p, $T_p = \{t_1, t_3\}$, and $P_{T_p}(t_1) > P_{T_p}(t_3)$.

STEP 2: Identify P_k, the key place set of T_p, and $C_k(P_k)$, the key colour set of P_k.

$\bullet t_1 = \{p_{11}, p_{21}, p_{31}\}$,

$\bullet t_3 = \{p_{31}\}$,

$P_k = \bullet t_1 \cup \bullet t_3 - \bullet t_1 \cap \bullet t_3 - [\bullet t_3] =$
$\{p_{11}, p_{21}, p_{32}\} - \{p_{31}\} - \Phi = \{p_{11}, p_{21}\}$.

Furthermore:

$C_k(p_{11}) = \{PROCCESS\}$,

$C_k(p_{21}) = \{PROCCESS\}$.

So: $C_k(P_k) = \{PROCCESS, PROCCESS\}$.

STEP 3: Modify the CPN model, Increase a "counter place" to calculate tokens in key place set.

STEP 3.1: Increase variables for "counter place" and trigger function for transition with lower priorities.

According to $C_k(P_k) = \{PROCCESS, PROCCESS\}$ and $|C_k(P_k)| = 2$, added a "counter place" with 2-tuples in the model for p_{11} and p_{21}. Defined variables and trigger function by CPN ML as follows:

```
//new colorset for "counter place" with two-tuples
    colset INTLIST = product INT * INT;
    var n1,n2:INT;
    fun tran(counts: INTLIST) =
```

```
let
  val count1 = #1 (counts);
  val count2 = #2 (counts);
in
//modify expression according actural condition
  not(count1 <>0 andalso count2 <>0)
end
```

STEP 3.2: Increase "counter place" for key place $P_k = \{p_{11}, p_{21}\}$ in CP-net model, with definition of colour set and initial value.

Increase "counter place" *count*, with colour set INTLIST. Because the initial count of the key colour PROCCESS in p_{11} and p_{21} are all 0, the initial value of "counter place" *count* is (0,0).

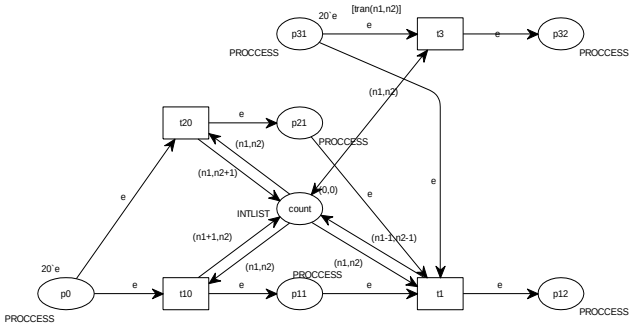

FIGURE 5 Model with priorities with $|P_k| \geq 1$ and $|C_s(P)| > 1$

STEP 3.3: Do as follows for each $\forall p \in P_k$: if the relative preset of the key place p is not empty, add two arcs from "counter place" *count* to ${}^{\bullet}\overline{p}$; and if the relative postset of the key place p is not empty, add two arcs from "counter place" *count* to $\overline{p}^{\bullet}$. Added arcs describe the change of tokens in key place *Count*, the "counter place", looks like the format (n_1, n_2) . And n_1 showed the change of p_{11} , n_2 records the change of p_{21} . Furthermore, changed in adding arcs and the arc functions (as shown in Figure 5).

STEP 3.4: If there is no outcoming arc from "counter place" *count* to other transitions with lower priorities in same group, added one bi-directional arc with function (n_1, n_2) .

STEP 3.5: Added trigger function in all transitions with lower priorities.

In this example, added trigger function $tran(n_1, n_2)$ for transition t_3 .

5 Practise example

Example 3: The systems have a main program Proccess, and two external interrupts $INTR_1$ and $INTR_2$, which have the priorities relationships that the priorities of $INTR_1$ is higher than $INTR_2$, namely $P_{INTR1} > P_{INTR2}$. The question is how to construct a CPN model to meet interrupts priorities.

The main process *Proccess* set interrupts on or off. The place *INTR* managed all the interrupts that is, when *Proccess* set the interrupt on, it send semaphore $intr_1$ to transition on_intr_1 in order to enable the active interrupt. Otherwise, when it set the interrupt off, it remove $intr_1$ from transition on_intr_1, thus disabled the interrupt, as shown in Figure 6.

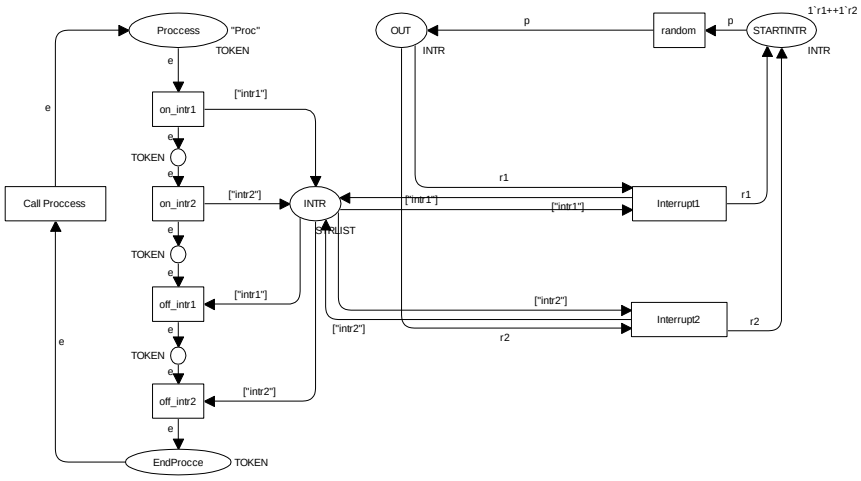

FIGURE 6 Interrupt model M_3 without priorites

The place *STARTINTR* simulated the external interrupts, the transition *random* control the happening of interrupts randomly, and the place *Out* represented the current enabled interrupts. The interrupt conditions are:

(i) $INTR_1$ had been enabled;

(ii) The existence of the external interrupt $INTR_1$, then $Interrupt_1$ could run. However, the model could be shown as FIGURE 6, although given the current disconnect, turn control to an external interrupt occurs, but not showing the priorities of relations between $INTR_1$ and $INTR_2$.

If omitted other unrelated contents, the interrupt model could be minimized, as shown in Figure 7.

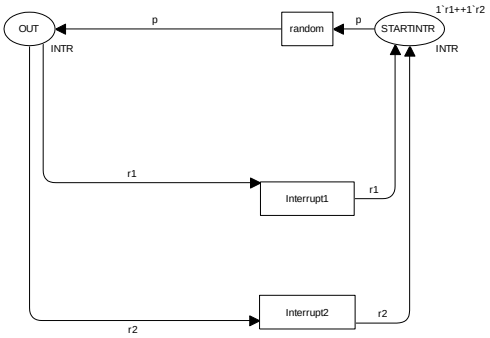

FIGURE 7 Minimized interrupt model M_4

The minimized interrupt Model M_4 use the above algorithm, as show as Section IV.

STEP 1: Identify group of transitions with priorities T_p .

In Figure 7, transition set is $T = \{random, Interrupt_1, Interrupt_3\}$. The group of enabled transitions with priorities is T_p .

$T_p = \{Interrupt_1, Interrupt_2\}$,

So, $P_{T_p}(Interrupt_1) > P_{T_p}(Interrupt_2)$.

STEP 2: Identify P_k , the key place set of T_p , and $C_k(P_k)$, the key colour set of P_k .

$^{\bullet}Interrupt_1 = \{out\}$,

$^{\bullet}Interrupt_2 = \{out\}$.

Thus,

$P_k = {}^{\bullet}Interrupt_1 \cup {}^{\bullet}Interrupt_2 -$
$^{\bullet}Interrupt_1 \cap {}^{\bullet}Interrput_2 - [{}^{\bullet}Interrupt_2] = \Phi$.

Namely, it became an unsolvable problem by using the above algorithm.

Secondary transitions, *call_intr1*, *call_intr1*, and places, *OUTING1*, *OUTING2*, could be introduced to the previous model M_4. Furthermore, place *OUT* would be divided into two places OUT_1 and OUT_2. Thus, the model M_4 could be changed as M_4', shown in Figure 8.

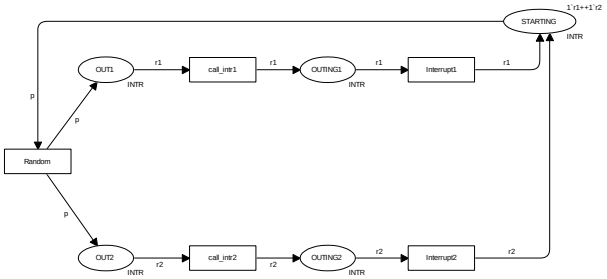

FIGURE 8 Auxiliary Model M_4'

$^{\bullet}Interrupt_1 = \{OUTING_1\}$,

$^{\bullet}Interrupt_2 = \{OUTING_2\}$.

Thus,

$P_k = {}^{\bullet}Interrupt_1 \cup {}^{\bullet}Interrupt_2 - {}^{\bullet}Interrupt_1 \cap {}^{\bullet}Interrput_2 -$
$[{}^{\bullet}Interrupt_2] = \{OUTING_1, OUTING_2\}$.

Next,

$C_k(OUTING_1) = \{INTR\}, C_k(OUTING_2) = \{INTR\}$

So, $C_k(P_k) = \{INTR, INTR\}$.

In the model M_4', when the places, $OUTING_1$, and $OUTING_2$, being changed, they could affect trigger priorities of transitions $Interrupt_1$ and $Interrupt_2$.

STEP 3: Modify the CPN model, increasing one "counter place" to calculate tokens in key place set, as shown in Figure 9.

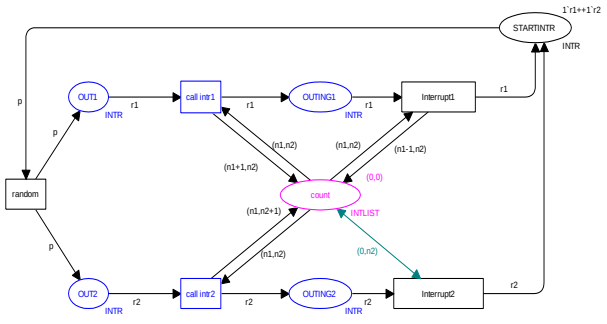

FIGURE 9 Partial interrupt model with priorities

Add the modified partial model to the original model to form a complete interrupt model with priorities M_5, as shown in Figure 10.

In the complete model, the main process *Proccess* could send semaphore to the place *INTR* to control whether the interrupts are enabled. Moreover, the transition $Interrupt_1$ or $Interrupt_2$ could be tangled only when outing interrupts signal is enabled. Meantime, only the transition $Interrupt_1$ could be triggered although it and $Interrupt_2$ could be enabled simultaneously, namely, $Interrupt_1$ have higher priorities than $Interrupt_2$.

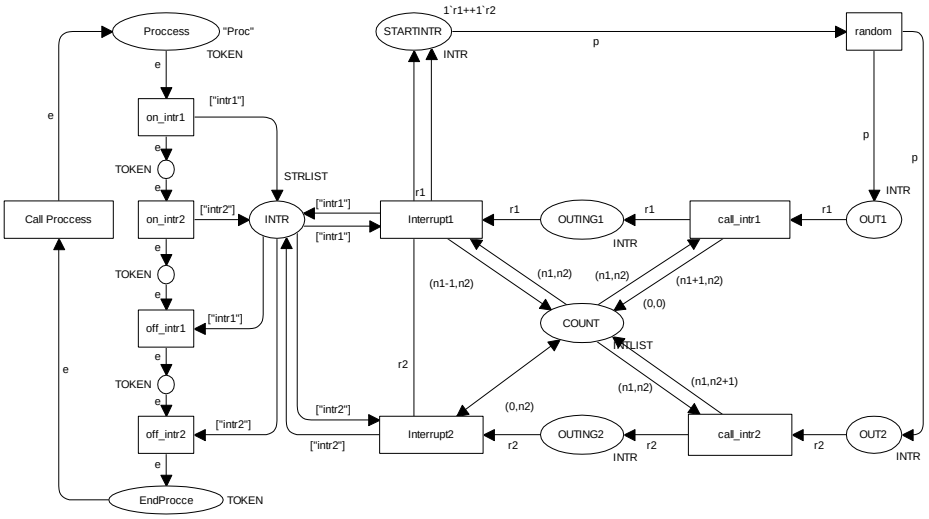

FIGURE 10 Complete interrupt model with priorities

6 Working outlook

This paper researched the CPN model with transition priorities in Group. When the original model has lower complexity, that was, $|P_k|$ and $|C_k(P_k)|$ is small, algorithm for transition with priorities is better. However, this algorithm only addressed transition priorities under enabling condition, not under certain conditions. After that, it could expand the research work in this regard. Furthermore, due to "count place" need to connect bi-directional arc to multiple transitions, making the more complex model structure, reducing the complexity of the model is also the focus of future research.

Abstract

Form-finding is the important problem to be solved in the cable structure analysis, to the different forms of loads, the direct iterative method is used to determine the initial configuration of the cable structures. Horizontal tension or cable tension is used as iterative convergence condition, the form-finding of the cable is researched under its own gravity, uniform ice and non-uniform ice load. As for the multi-span transmission lines, two conditions of uniform ice and non-uniform ice loads on the whole span were analysed. The results of initial configuration are consistent with the analytical method, which verified the correctness of the direct iterative method, under the condition of non-uniform ice load, the stress of conductor is larger than the maximum stress, which is very dangerous in the actual operation.

Keywords: mechanical characteristics, form-finding, uniform ice, non-uniform ice, finite element method

1 Introduction

In the design of transmission lines, the sag, stress and length of transmission lines are very important parameters, which are the main contents to the mechanics research of transmission lines, this is because the sag and stress directly affect the safety of operation, the small changes and error of cable length will make considerable change to the sag and stress, form-finding is the primary problem to be solved before the analysis and calculation of the cable structures, which is the fundamental prerequisites for dynamic response. Currently, there are four methods for the form-finding analysis of cable structures:

1) The nonlinear finite element method [1,2];

2) The force densities method [3];

3) The dynamic relaxation analysis of form-finding [4, 5];

4) The exact element method [6].

The nonlinear finite element method is most widely used for form-finding. In previous study, the dynamic analysis of cable structures is often assumed to the initial curve with simple shape, the uniform ice and some other non-uniform distributed loads are considered as the ideal uniformly distributed loads, but in many cases, the thickness of ice is not same along the conductors, especially in some micro topography and micro climate area, transmission lines have large elevation difference and big spans, the conductor suffers serious non-uniformly distributed load [7]. Such as the jumping induced by transmission line ice-shedding [8], the research for the dynamic response of ice-shedding on bundled transmission lines [9], and vibration of bundled conductors following ice shedding [10]. The dynamics analysis of the overhead transmission lines with non-uniformly distributed load is accurate based on form-finding, which will be very important to the design of the cable structures.

2 The load distribution of cable structures

The transmission lines belong to one kind of cable structures, the theory of cable structures are based on two assumptions:

1) The cable is flexible: it neither suffers the pressure nor bending;

2) The material of the cable structures follows Hooke's law.

Figure 1 shows an infinitesimal piece of cable, H is horizontal component of the tension T in the tangential direction. V is the vertical component of the T, q_x is the distributed load along the x direction, q_y is the distributed load along the y direction.

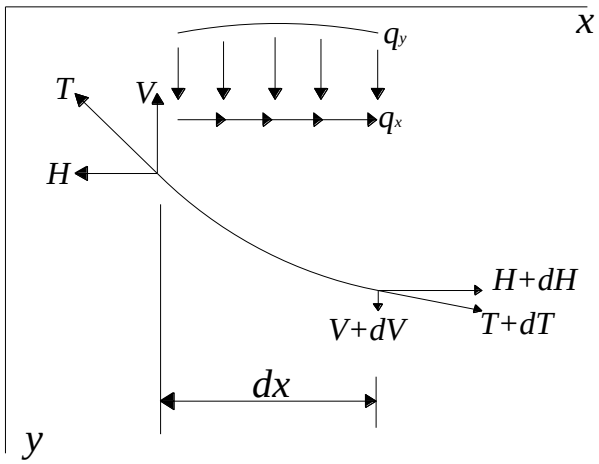

FIGURE 1 Equilibrium of an infinitesimal piece of cable

*Corresponding author e-mail: liuyuejun@163.com

The equilibrium equation of the horizontal direction is:

$$\frac{dH}{dx}+q_x=0\,. \tag{1}$$

The equilibrium equation of the vertical direction is:

$$\frac{dV}{dx}+q_y=0\,. \tag{2}$$

As $V=H\dfrac{dy}{dx}$ Equation (1) and (2) can be transformed to:

$$\frac{dH}{dx}+q_x=0\,, \tag{3}$$

$$\frac{d}{dx}\left(H\frac{dy}{dx}\right)+q_y=0\,. \tag{4}$$

Equation (3) and (4) are the governing differential equations of transmission line shape curve. The task for form-finding is to determine the transmission line shape curve, which is to obtain the equilibrium of the applied pretension and external loads by adjusting the form of cable under the given boundary condition.

The uniformly distributed load on the cable structure is generally divided into two forms:

1) uniformly distributed load along chord line of the cable, the shape of cable is parabola;

2) uniformly distributed load along arc length of cable, the shape of cable is catenary, such as the shape of the cable under the action of gravity.

According to the theoretical analysis, the smaller the sag of cable is, the smaller difference of two forms is, to the actual transmission lines, the sag of cable is very small, when the uniformly distributed load is along chord line of the cable, the error of sag is small, it can be received by engineering. The gravity of transmission lines is uniformly distributed along arc length of cable, therefore, under the action of its own gravity, the shape of the transmission line is catenary, rather than a parabola. When the span is small, the sag-span ratio is smaller, the difference is the smaller [11], generally in engineering, if the sag-span ratio is less than 1/8 [12], it can get enough precision of calculating with a parabolic curve.

3 The overall analysis of cable structures

Figure 2 shows a typical joint *J*, Fzie is vertical force of the endpoint i in the element *e*, (*i* changes with different element), *PJ* is the concentrated force acted on the joint *J*.

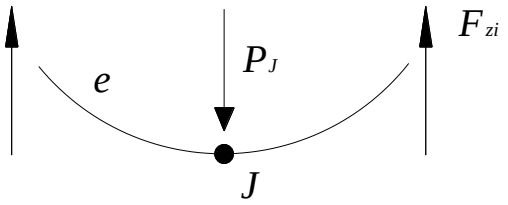

FIGURE 2 Joint J

The vertical equilibrium equation can be written as:

$$\sum_{e_J}F_{zi}^{\,e}-P_J=0\,, \tag{5}$$

where, e_J presents the element connecting with joint *J*, Equation (1) can be written as:

$$\sum_{e_J}\left(k^e_{\,i1}z^e_{\,1}+k^e_{\,i2}z^e_{\,2}\right)=P_J+\sum_{e_J}P_{Ei}^{\,e}\,. \tag{6}$$

According to the overall integration method, the equation of the global stiffness matrix is:

$$KZ=P\,, \tag{7}$$

where *K* is the global stiffness matrix, *P* is the resultant force from P_J and P_{Ei}^e, *Z* is vector of vertical coordinates.

The state equation of transmission lines is:

$$\sigma_{02}-\frac{E\gamma_2^{\,2}l^2\cos^3\beta}{24\sigma^2_{\,02}}=\sigma_{01}-\frac{E\gamma_1^{\,2}l^2\cos^3\beta}{24\sigma^2_{\,01}}-\alpha E\left(t_2-t_1\right), \tag{8}$$

σ_{01}, σ_{02} - the stress of transmission lines at the lowest of sag under two kinds of state, MPa;
γ_1, γ_2 - the specific load of transmission lines under two kinds of state;
t_1, t_2 - the temperature of the transmission lines under two kinds of state;
l, β - the span and the angle of differential elevation;
α, E – the temperature expansion coefficient and elastic modulus.

4 The basic principles of form-finding for transmission line

The direct iterative method is used to determine the initial configuration of the cable structure, the basic principles of the direct iterative method is connecting the chord line as the model, using actual material properties and real constants, and set a small initial strain, and then applying the gravity which distributed along the arc length, and gradually update the finite element model, the horizontal tension or cable tension is chose as iterative convergence conditions, the final result is initial deformation of cable structures under its own gravity, the basic process is showed as Figure 3:

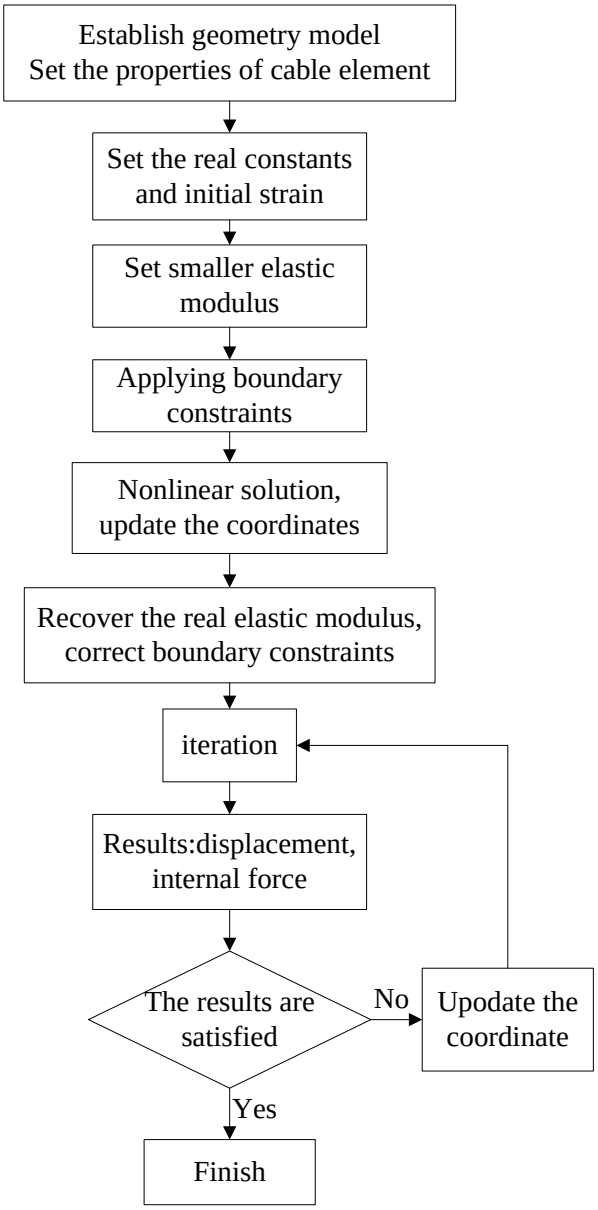

FIGURE 3 The flow chart of form-finding

5 The finite element model of the single span transmission conductor

5.1 THE ESTABLISHMENT OF THE CONDUCTOR MODEL

The finite element method of conductors is transforming the infinite degrees of freedom into a limited degree of freedom. The conductor should be discreted, the stiffness matrix is established through the appropriate shape function of link element, the global stiffness matrix is integrated, the basic equation is established according to the node displacement vector and the node load vector, applying the boundary conditions, the node displacement can be got by solving the basic equations.

The transmission line belongs to a kind of flexible cable structures, which has strong geometric nonlinearity, the geometric characteristics of small strain and large rotation will make stiffness matrix change nonlinearly, the stiffness matrix of structure becomes the function of geometric distortion, the form-finding of transmission lines should open large deformation options in the ANSYS and set the time step, the stress effect should be considered in order to ensure the accuracy of the results.

The form-finding for the transmission lines is analysed by the software ANSYS, the link 10 unit is chose to simulate the lines, the model is connecting a straight line between two points, the straight line is divided into a number of straight link 10 units, the two points are imposed fixed constraints, the gravity loads are imposed along the arc length. The equilibrium configuration of the transmission lines has got under the action of the gravity load, the form-finding of iced transmission lines is based on the equilibrium configuration under gravity. Set nonlinear solution selection. The equilibrium configuration of iced transmission lines is solved, the form-finding of transmission lines is finished under the action of ice load.

Select an overhead transmission line with different height of suspension points, the span is l = 1000 m, the elevation difference between the two suspension points is h = 40 m, the conductors choose LGJ – 400/35, the technical parameters are shown in Table 1. The ice thickness is 20 mm, the weight per unit length is 15.02 N/m, and the ice density is 0.9 g/cm^3. The mechanical parameters of ice are shown in Table 2.

TABLE 1 the technical parameters of conductor

Number of conductor	Cross-sectional area (mm^2)	Tensile force of calculation (N)	Mass per unit length (kg/km)	allowable stress [σ0] (Mpa)	Diameter (mm)
one	425.24	103900	1349	92.8	26.82

TABLE 2 the mechanical parameters of ice

Variables	Numerical value
The thickness of ice (mm)	20
Density (kg/mm^3)	9×10^{-7}
Poisson's ratio	0.3
The damping ratio	0.1
Coefficient of Comprehensive elasticity (Gpa)	10
Coefficient of Comprehensive expansion (1/°C)	50×10^{-6}

5.2 THE FORM-FINDING OF TRANSMISSION LINES UNDER THE ACTION OF GRAVITY

The conductor is divided into 100 units, the horizontal tension or cable force is the convergence criterion for iteration, the displacement vector diagram of conductor under gravity load as shown in Figure 4, it can be seen that

the biggest displacement vector of conductor is 0.654 m, the conductor tends to equilibrium state.

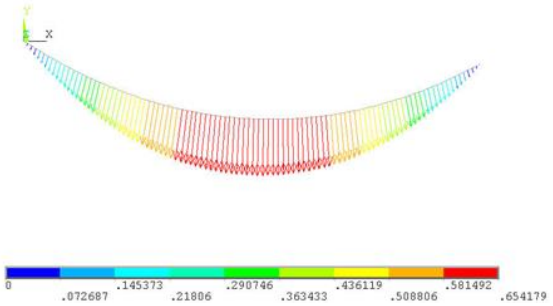

FIGURE 3 The displacement vector diagram of conductor under gravity load (m)

5.3 THE FROM-FINDING OF ICED TRANSMISSION LINES

In many cases, the ice on the conductor is not uniform, it is assumed that the weight is equal with uniform ice and non-uniform ice, the weight of ice on the conductor is measured by the ellipse method or the total weight method, the thickness of uniform ice is 20mm, distributing along the span of the conductors, the ice thickness of different position of is different, which makes the changes of sag and stress are also different, the transmission line is divided into five sections under the action of non-uniform ice load, the horizontal projection length of each section is 200m, the distribution of ice is shown in Table 3.

TABLE 3 The distribution of ice

the case of ice		**the section of ice distribution (mm)**				
		1	*2*	*3*	*4*	*5*
uniform ice		20	20	20	20	20
non-uniform ice	A	30	25	20	15	10
	B	20	30	25	15	10
	C	10	20	30	25	15

Through calculation, the displacement (namely the sag) and stress can be got, analytical values and nonlinear finite element simulation values of representative nodes are listed in Tables 4 and 5 under the condition of self-gravity. It can be seen that the absolute value of the difference between the simulation value with the analytical value is very small, which shows that application of the finite element method to find form of transmission lines is correct and feasible.

The sag of analytical and simulation value are shown in Table 4, the absolute value of difference is very small, It illustrates that the finite element method is feasible for simulating from-finding of transmission lines. The sags of iced transmission lines at all the points are larger than bare conductors. It can be seen from that the sag and stress of transmission lines changed with different kinds of the non-uniform ice conditions. Judging from its variance, the change of stress at all points is different with different non-uniform ice conditions, the biggest change appears at both ends and the central span of the conductor.

The deformation diagrams of transmission lines under uniform ice and non-uniform ice are shown in Figure 5-8, the sag and stress have changed a lot, with the increase of elevation difference, the difference of sag and stress becomes larger and larger. The allowable stress of conductor LGJ – 400/35 is 92.8 Mpa, maximum stress does not exceed the allowable stress under uniform ice and condition A, B. But to the condition C, the maximum stress

of the iced transmission line at the node 101 is larger than the allowable stress, which will have risk in the actual operation.

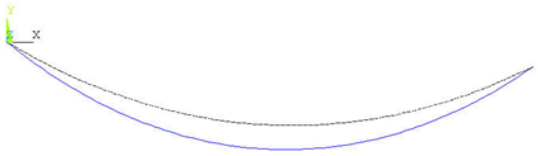

FIGURE 5The deformation diagrams of transmission lines under uniform ice

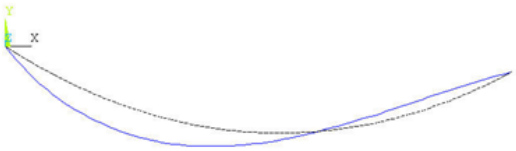

FIGURE 6 The deformation diagrams of transmission lines under ice condition A

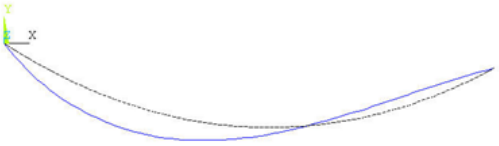

FIGURE 7 The deformation diagrams of transmission lines under ice condition B

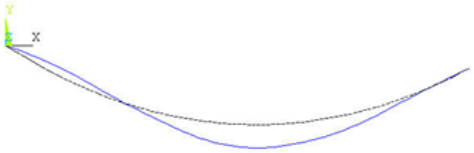

FIGURE 8 The deformation diagrams of transmission lines under ice condition C

6 The form-finding of multi-span transmission lines

6.1 THE MECHANICAL CHARACTERISTICS OF MULTI-SPAN TRANSMISSION LINES

Figure 9 shows the multi-span transmission lines, the force of point A is shown in Figure 10, it does not consider all the friction in the transition zone, it can be obtained the following equilibrium equation without considering the friction.

$$T_1 = T_2. \tag{9}$$

In general $\theta_1 \neq \theta_2$, therefore:

$$H_1 = T_1 \cos\theta_1 \neq T_2 \cos\theta_2 = H_2.$$

Applying the nonlinear finite element method to find form of transmission lines, the horizontal tension is the iterative condition (horizontal tension=the average tension stress by the cross-sectional area), for the multi-span transmission lines, the horizontal tension is unequal. The horizontal tension to each adjacent span can be calculated by Equation (9). If the error of horizontal tension is smaller than 5%, update the model with smaller numerical value, or update with a large numerical value.

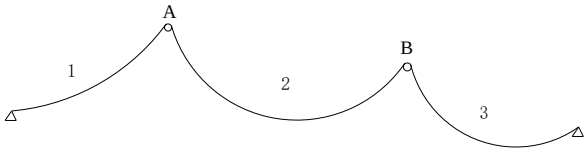

FIGURE 9 The multi-span transmission lines

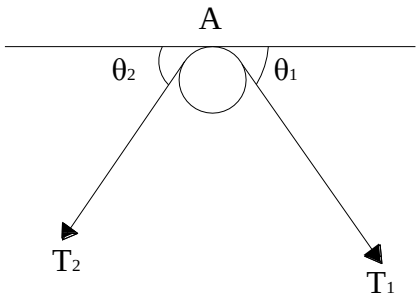

FIGURE 10 The force of point A

6.2 THE EXAMPLE OF FORM-FINDING FOR MULTI-SPAN TRANSMISSION LINES

With reference to the above model parameters of single span transmission line, the model of three consecutive transmission lines was set up, in the actual transmission lines, the adjacent spans are connected by insulators, so the joints of two middle spans are set as hinge constraint, the ends of the lines are used fixed constraint, the Y direction of degrees of freedom at the joints of two middle spans are restrained. Ice conditions of the transmission lines are divided into four kinds of working conditions, which is shown in the Table 6. The thickness of uniform ice is 20 mm. The deformation diagrams of transmission lines under uniform ice and non-uniform ice are shown in Figure 11-14. The distribution of sag has changed a lot with uniform and non-uniform ice, the sag increased in the condition of 2-3, which make the sag of the adjacent span changed, which has a significant impact on the normal operation of transmission lines.

TABLE 6 The ice conditions of three consecutive transmission lines

FIGURE 13 The deformation diagrams of the second spans under uniform ice

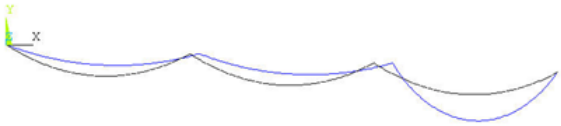

FIGURE 14 The deformation diagrams of the third spans under uniform ice

7 Conclusion

1) According to the different forms of load on cable structure, the form-finding of the cable is researched under its own gravity, uniform ice and non-uniform ice load. As for the multi-span transmission lines, two conditions of uniform ice and non-uniform ice loads on the whole span were analysed, which provide premise for the dynamics analysis of transmission lines, the accuracy of form-finding will seriously affect the results of dynamic response.

2) It can be seen that the absolute value of the difference between the simulation and the analytical value is very small, which shows that application of the finite element method to find form of transmission lines is correct and feasible. The sags of iced transmission lines at all the points are bigger than bare conductors. For the non-uniform ice conditions of A, B and C, it can be seen from that the sag and stress of transmission lines changed with different kinds of the non-uniform ice conditions. Judging from its variance, the change of stress at all points is different with different non-uniform ice conditions, the biggest change appears at both ends and the central span of the conductor.

3) The sag and stress have changed a lot between the conditions of uniform ice and non-uniform ice, with the increase of elevation difference, the difference of the sag and stress becomes larger and larger. The allowable stress of conductor LGJ – 400/35 is 92.8 Mpa, the maximum of the iced transmission line stress does not exceed the allowable stress under uniform ice and condition A, B. But to the condition C, the maximum stress at the node. 101 MPa is larger than the allowable stress, which will have risk in the actual operation.

Abstract

The ECG signal contains a lot of interference in the mobile ECG monitoring system. Reasonable selection of signal filtering and QRS wave detection method are the key to ECG signal analysis. According to the characteristics of ECG signals, the design of low-pass filtering and the improved median filter that can filter the interference has been conducted in the paper. Meanwhile, addressing to the limitation generated by selecting and fixing the median threshold using the traditional differential slope method, the paper has proposed the adaptive dynamic threshold and used quadratic difference algorithm to process signal in order to obtain R wave, and then locate Q and S wave based on R wave location. In addition, combining the characteristics of the QRS wave group, judgments on the missing and over detection are conducted, so that the algorithm is robust and has good fault-tolerant ability. The experimental results show that, this algorithm can not only satisfies the need of the real-time QRS wave detection, but is also more suitable for the transmission and processing of ECG signals in mobile ECG monitoring.

Keywords: mobile ECG signal, QRS detection, algorithm

1 Introduction

Mobile ECG monitoring device can quickly detect the real-time dynamic ECG signal to provide emergency ambulance, disease surveillance, medical advice and guidance services for users. Its application prospect is thus very promising [1].

Taking into account that the mobile ECG detection method shall be easily used by the users, the detection of the lead ECG signal is conducted by pressing the metal conductor with both thumbs. The Dynamic ECG signals obtained by this method contain a large amount of 50HZ interference, baseline drift, EMG interference and motion artifacts, as well as noise interference [2]. Various noises degrade the accuracy of diagnosis, and thus suitable methods must be used to conduct the filtering prior to the calculation of the heart rate data [3].

In this paper, the original data is received by the mobile phone from the Bluetooth transmission module. Raw data is then filtered by FIR low pass filter. Low frequency interferences, such as baseline drift, are removed through improved median filter. The smoothed data is finally returned. The said process is shown in Figure 1.

Since the mobile ECG monitoring equipment requires the real-time processing and transmission of ECG information [4], it is very important to design an accurate and fast heart rate detection algorithm.

At present, there are various ECG detection algorithms, such as difference vector analysis method [5], template matching method [6], wavelet transform method [7, 8] and neural network method [9, 10], etc. The differential threshold method has a simple algorithm which is fast in the processing speed and easy to be implemented in engineering [11, 12]. The template matching method is simple in principle, but it is very sensitive to high frequency noise and baseline drift [13, 14]. Wavelet transform method has excellent characteristics of time frequency localization, as well as high detection accuracy, but the amount of calculation is huge, which is not suitable for real-time processing [15, 16]. The neural network method can achieve a very good effect of discrimination, but its training time is long, and its real-time performance is poor [17, 18].

The said methods have both advantages and disadvantages. Addressing to the limitations caused by selecting and fixing the threshold in the traditional difference method, an adaptive dynamic threshold is set in this paper according to the signal characteristics. First, the initial data is intercepted and its first order difference is calculated, from which the initial threshold and amplitude threshold are obtained. Then, dynamic threshold adjustment is made by self-learning method. Finally, R wave is located according to the threshold. Q, R, S wave is then accurately localized based on QRS waveform characteristics.

2 Filtering algorithm

2.1 LOW-PASS FILTER DESIGN

There are two ways to design low-pass filter design: one is IIR - infinite impulse response filter, and the other is FIR - finite impulse response filter. The difference lies in: IIR filter can get very high selectivity with the lower order, and it uses less memory, less calculations, and therefore it is not only economic but high in efficiency. However, high efficiency costs nonlinearity of the phase; hat is the better the selectivity, the more serious the nonlinearity is. In contrast, FIR filter can obtain a strictly linear phase. However, a higher order is required to get a certain selectivity, which asks for more memory and longer operation. As well, the signal delay is relatively large. In view of the fact that the mobile ECG signal has a strict requirement on the linear phase, and its stability in operation must be good, and noise power of the output signal caused by calculation error shall be small, as well as its nature of real-time shall be strong and operation speed shall be high [19], in this paper the window function method is adopted to design the filter [20].

Let the expected approximation response function of filter frequency be $H\left(e^{j\omega}\right)$, $h_d\left(n\right)$ be the corresponding unit impulse response, $H\left(z\right)$ be a system function. Then we can have the following equation:

$$H\left(e^{j\omega}\right)=\sum_{n=0}^{N-1}h_d(n)e^{-j\omega\omega}, \tag{1}$$

$$h_d\left(n\right)=\frac{1}{2\pi}\int_{-\pi}^{\pi}H\left(e^{jw}\right)e^{jwn}d\omega, \tag{2}$$

$$H\ (\mathrm{z})=\sum_{n=0}^{N-1}h(n)z^{-n}. \tag{3}$$

Generally speaking, $h_d\left(n\right)$ is infinitely long, and thus it needs an approximation of $H\left(e^{j\omega}\right)$. When the window function design method is adopted, the ideal filter unit sampling response and window function can be used to conduct the filter design:

$$h(n)=h_d(n)w(n), \tag{4}$$

where $\omega\left(n\right)$ is a window with a finite length, with a value of 0 outside the interval of $0 \le n \le N$, and it is symmetric with the middle point:

$$\omega\left(n\right)=\omega\left(N-1-n\right). \tag{5}$$

The frequency response can be obtained by the convolution theorem:

$$H\left(e^{j\omega}\right)=\frac{1}{2\pi}\int_{-\pi}^{\pi}H_d(e^{j\theta})W\left(e^{j(\omega-\theta)}\right)d\theta. \tag{6}$$

The degree of approximation of the frequency response of the filter designed using the window function method to the ideal response is determined by two factors: $\omega\left(e^{i\omega}\right)$ the width of the main lobe, and $\omega\left(e^{i\omega}\right)$ the amplitude of the side lobe.

In order to satisfy the requirement of stopband attenuation index, and at the same time to ensure the effective denoising while making the calculation time be the shortest, the low-pass filter of 34 orders and cutoff frequency of 35Hz is selected in this paper to remove the interference noise. The amplitude frequency characteristics is shown in Figure 2, and its denoising effect is shown in Figure 3.

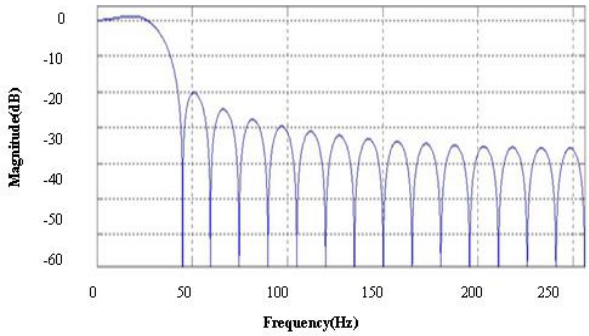

FIGURE 2 The low-pass filter characteristics

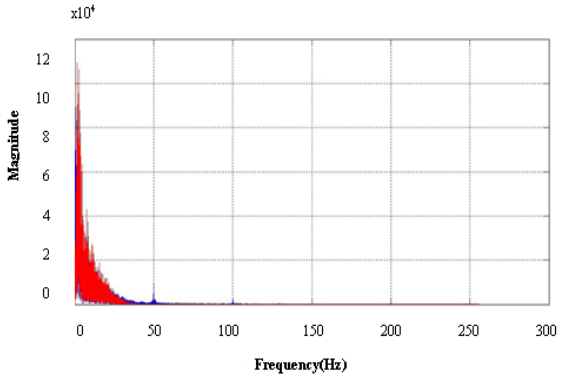

FIGURE 3 Low-pass filtering effect diagram

The red part is filtered spectrum, and the blue one is the original signal spectrum in Figure 3, from which we can see that the design of the low-pass filter can well remove the 50HZ frequency interference and quadratic harmonic of 100HZ frequency.

2.2 MEDIAM FILTER DESIGN

In addition to the filtering of the high frequency interference, a filter must be designed to remove the baseline drift, and the DC component.

Since the band mobile ECG baseline drift is less than 2HZ, if the filter cutoff frequency is too low, it cannot properly eliminate the baseline drift, but if the cutoff frequency is chosen too high, it would make the S-T segment definition waveform distort, as shown in Figure 4.

In Figure 4, the Q wave passing a high pass filter weakens downward, and the S wave rises up and T wave also weakens very significantly. Spectral contrast diagram before and after the filtering by the high-pass filter is shown in Figure 5, where the red part is filtered signal spectrum, and the blue part is the original signal spectrum. The spectrum chart shows that the filtering effect lower than 10Hz band is very poor. If the 0-2HZ band is to be filtered, higher order high pass filter would be needed, but the resulting high time-consumption is not suitable for mobile ECG detection. Hence, we turn to adopt the improved median filtering method.

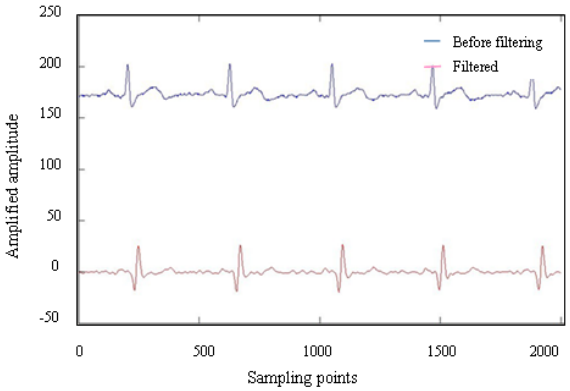

FIGURE 4 The filtered comparison chart in high-pass filter

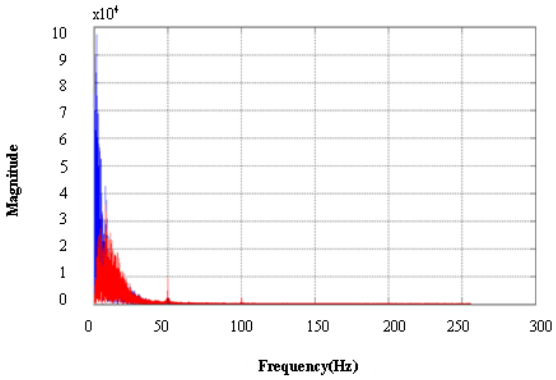

FIGURE 5 High-pass filter effect spectrum diagram

The traditional median filtering method is based on a value of $X(i)$ as the center and the odd point nearby as the window. The points of odd numbers are sorted, and then the median is taken as the new value of $X(i)$, and so on. The window length is generally in odd numbers like 5 or 7.

The improved median filtering method is: the window is taken at the centre point whose length is marked by an odd number larger than or equal to 127 The data of window lengths shall be sorted to obtain the median,, and then the new median is subtracted from the original median point, thus removing the DC component. It is also quite inhibiting against baseline drift.

The specific algorithm is as follows:

$X(i)$ is data of No. i sampling point of the original signal. Through the $X(i)$, values from the $X(i\text{-}63)$ to $X(i+63)$ are sorted to take the median value, *mid*. Then $Y(i)$ is take as $X(i)$ - mid (i.e. $X(i)$ minus *mid*), where $Y(i)$ is No. i sampling signal after the median filtering.

Spectrum comparison chart before and after the median filtering is as shown in Figure 6.

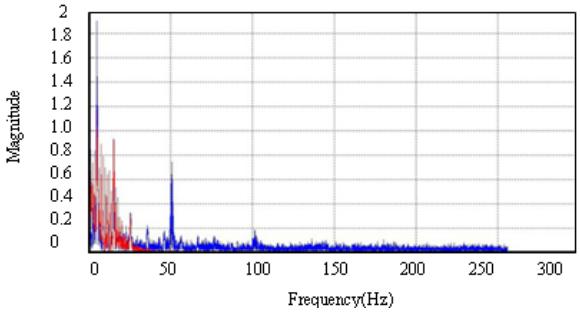

FIGURE 6 Median filter effect spectrum diagram

The filtering results of low-pass filter and median filter as shown in Figure 7.

As the figures show, the improved median filtering method can effectively eliminate the DC component, and the location of the baseline in Figure 7 effectively returns to zero. The algorithm is simple, and less time-consuming, which is suitable for low frequency filtering of the mobile ECG signal.

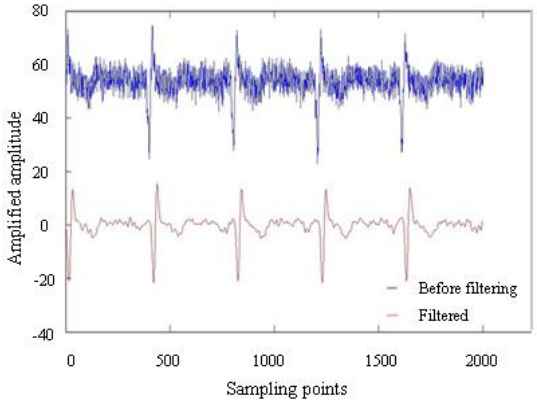

FIGURE 7 The filter effect results

2.3 SIGNAL SMOOTHING

The average smoothing filter is suitable for filtering the signals that have random noise, and the smoothing effect is obvious. However, if the window length selected is too large, the peak clipping phenomenon would be serious, because the average obtained in the apex of R wave and the surrounding points can reduce R wave characteristics. On the other hand, if the window length is too small, it will greatly reduce the smoothing effect. In order to improve the method of average smoothing filter, the average of several points around a point is taken as the new value of this point:

$$Y(i)=\big(Y(i-3)+Y(i-2)+Y(i-1)+Y(i)+ Y(i+1)+Y(i+2)+Y(i+3)\big), \tag{7}$$

where the window length is determined according to the 7 sampling points.

3 QRS wave group detecting

3.1 DETECTION ALGORITHM

The key point to use the differential threshold method is to determine a reasonable detection threshold, but the R wave form and amplitude will vary due to detection of different objects. Therefore, it is difficult to find a unified detection threshold that is suitable for various objects to be detected. In order to solve this problem, this paper adopts the self-learning algorithm to build the detection threshold.

Set the divergent ECG signal as $x(n)$, the length of the signal is L. An improved differential algorithm is adopted to detect the QRS wave group:

$$y(n) = x(n+2) + x(n+1) - x(n-1) - x(n-2), \tag{8}$$

where, $n = 2, 3, ..., L-2$.

Take the first order difference of $X(n)$:

$$d(n) = x(n+1) - x(n), \tag{9}$$

where, $n = 1, 2, L-1$

It is known from Equation (8) that, obtaining the signal $y(n)$ from the five point difference will prominently display the characteristics of R wave. The judgment on the R wave is made by using the self-learning difference threshold conditions against $y(n)$. Combining the above with self-adaptive threshold set would preliminarily locate the R wave.

Equation (9) shows that $d(n)$ signal is obtained by conducting the first-order differential of the $y(n)$ signal. Corresponding relationship between the singular points of $y(n)$ in the $d(n)$ is established, and thus effectively confirm the R wave. The differential of zero crossing as well as the initial average amplitude thresholds left and right of R wave are calculated to accurately position the ECG QRS wave group.

In the actual detection, when a human body first contacts the electrode, an unstable phenomenon may occur. Through the pilot test, it is determined that the initial 6 seconds is the unstable period. In this paper, the ECG signal sampling frequency is 512HZ. Considering the data processing speed and data buffering problem, real-time computing takes the data collected within 2 seconds as the dynamic cycle. Figure 8 is the heart rate calculation flow chart, where DDmax and DDmin, AAmax are the initial maximum, minimum and maximum threshold, TH is the initial amplitude drop.

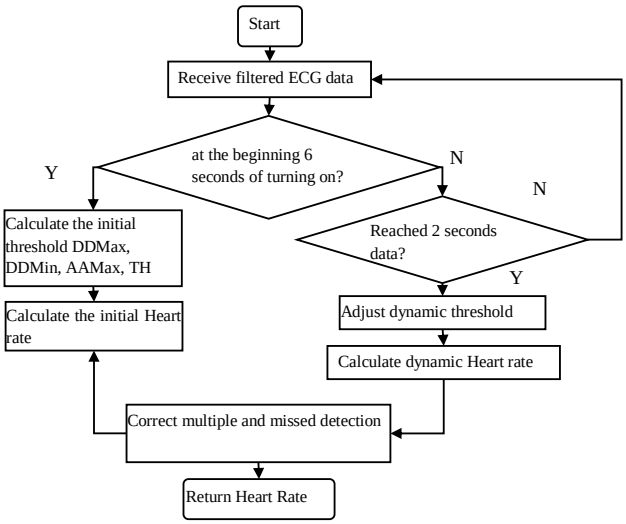

FIGURE 8 Heart rate calculation flowchart

3.2 ALGORITHM DESCRIPTION

3.2.1 Calculate the various initial thresholds

In this paper, X_i, the data in the initial 6 seconds of filtered $x(n)$, is divided into 3 sections, with the unit cycle taken as 2 seconds. Differential operation is conducted according to Equation (8) on each section to obtain the maximum difference value $D\max i$ and the minimum negative difference value $D\min i$ of its ECG data, as well as the maximum and minimum amplitude of the Xi signal. The arithmetic mean of $D\max i$, $D\min i$, $A\max i$ and amplitude difference ($A\max i$ - $A\min i$) is taken to obtain the initial thresholds of $DD\max$, $DD\min$, $AA\max$ and initial amplitude drop threshold TH. These thresholds can be expressed as the following equation:

$$\left.\begin{aligned} DD\max &= D\max/TH = 1/TH\left\{\frac{1}{3}\sum_{i=1}^{3} D\max i\right\} \\ DD\min &= D\min/TH = 1/TH\left\{\frac{1}{3}\sum_{i=1}^{3} D\min i\right\} \\ AA\max &= A\max/TH = 1/TH\left\{\frac{1}{3}\sum_{i=1}^{3} A\max i\right\} \\ TH &= (A\max - A\min)/TH = 1/TH\left\{\frac{1}{3}\sum_{i=1}^{3}(A\max i - A\min i)\right\} \end{aligned}\right\}, \tag{10}$$

where $D\max i = \max\left(Y\left[k\right]\right)$, $D\min i = \min\left(Y\left[k\right]\right)$, $A\max i = \max\left(X\left[k\right]\right)$,

$$Y\left[k\right] = X\left[k\right] + X\left[k-1\right] - X\left[k-3\right] - X\left[k-4\right].$$

The threshold of each unit cycle is jointly determined by the initial threshold, the maximum difference, the minimum difference and the maximum amplitude of the current section, *TH* is the parameter of the threshold. It can be adjusted according to the ECG R wave amplitude, and its value shall be an exponent with 2 as the base number.

3.2.2 Dynamic threshold adjustment

After the R wave is detected in the 6 seconds data using the initial threshold, the detection threshold is modified using the sliding average method. This paper takes every 2s as the dynamic threshold adjustment range. The newest threshold is jointly determined by the current segment threshold and the initial threshold. The update form of new threshold is:

$$\left.\begin{aligned} DD\max &= DD\max\cdot 2/3 + D\max\left[i\right]/3 \\ DD\min &= DD\min\cdot 2/3 + D\min\left[i\right]/3 \\ AA\max &= AA\max\cdot 2/3 + A\max\left[i\right]/3 \end{aligned}\right\}. \quad (11)$$

In the dynamic range, if the measured R wave amplitude *A*max[*i*] increases, the new threshold of the *AA*max new will increase. The threshold is dynamically adjusted, so the stability of the system is enhanced.

3.3 QSR WAVE DETECTION

3.3.1 R wave detection

After the detection threshold is obtained, the R wave detection shall be conducted on the signal of *y*(*n*). When the current difference value and the difference value of the next point is larger than the positive difference threshold *DD*max, and the current amplitude is larger than the amplitude threshold value *AA*max, this point shall be used as a starting point for the 160ms window. If there is a point that has difference value less than the negative difference threshold DDmin, the maximum peak point within the window shall be found as the peak of the R wave. Then the threshold in each sub cycle shall be adjusted according to the Equations (10) and (11), and the initial R wave is detected again with the new threshold. According to the "refractory period" principle in medical field [21], it is believed that the R wave won't appear again within 200ms, so we can skip the refractory period to conduct the detection. The R wave detection process is illustrated in Figure 9.

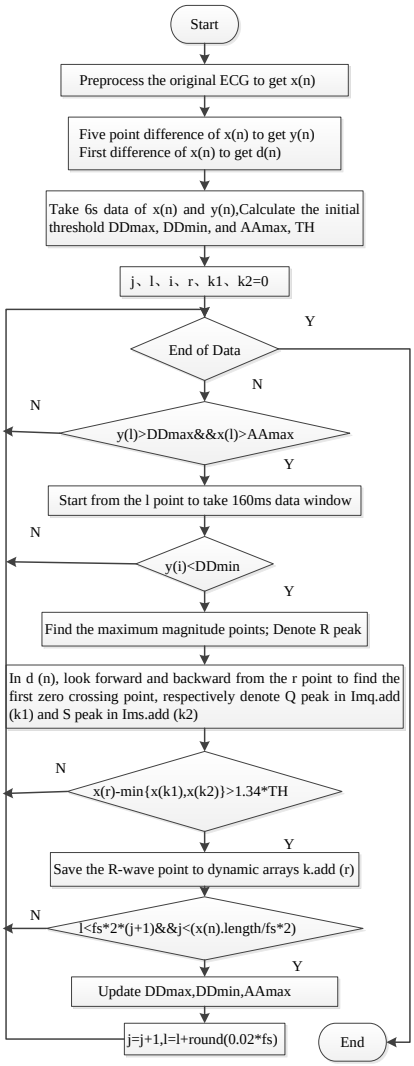

FIGURE 9 The R wave detection process

3.3.2 Q and S wave detection

After the detection of R wave is conducted, use a peak value of R wave point as the centre, forward and backward search the *Q* and *S* points.

In this paper, the first-order differential *d*(*n*) is used to detect the initial position detection of *Q*, *S* wave. The relation between the R wave and its corresponding *Q*, *S* wave position is: if the R wave value is the down zero (its value is negative) corresponding to the QRS wave group in the *d*(*n*). The *Q* wave shall appear in the first upward zero (its value is positive) before the R wave location; the *S* wave is the first upward zero (its value is positive) after the R wave position.

Because of the time - delay relation, the R wave position corresponds to the extreme position, k.get(*i*) in the *y*(*n*), and corresponds to the k.get(*i*)+3 position in the *d*(*n*). Similarly we can calculate the *Q* and *S* wave. The algorithm is as follows:

1) In the *d*(*n*), starting from k.get(*i*)-3, from back to front, search the first upward zero crossing point; mark its location as *Imq*(*i*).

2) In the $d(n)$, starting from k.get(i)+3, from front to back, search first upward zero; mark its location as $Ims(i)$.

3) Search the $Imq(i)$ and $Ims(i)$ in the $X(n)$; identify them as the positions of the Q and S wave, and calculate its amplitude.

4) Calculate the values of $Imq(i)$-3, $Imq(i)$-2, $Imq(i)$ corresponding to that in the $X(n)$, the minimum amplitude is Q wave position of $X(n)$ signal.

5) Calculate the values of $Imq(i)$-3, $Imq(i)$-2, $Imq(i)$ corresponding to that in the $X(n)$, the minimum amplitude is the S wave position of the ECG signal.

3.3.3 Processing the over detection and missing detection

In order to improve the detection accuracy, before the detection is completed, each RR interval (heartbeat interval) is judged. If the current RR interval is less than 0.6*RR, it is believed that there may be over-detections that need further treatment. If it is greater than 0.6*RR, and the sum of two adjacent RR clearances is less than 1.5*RR, the existence of over-detection would be confirmed. If over-detection is the case, the amplitude shall be re-adjusted, and the R wave is detected with the algorithm again to revise the detections. The process of fixing over-detection is shown in Figure 10.

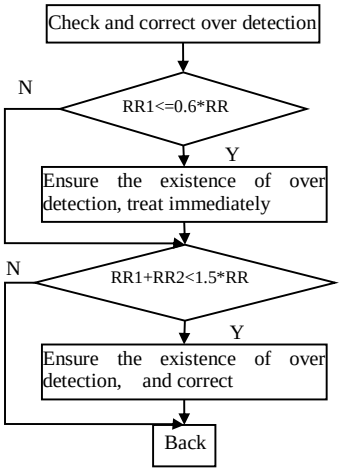

FIGURE 10 Over-detection process

In addition to over-detection, there may also be missing detection. The missing detection judging method is as follows: check whether the RR interval is greater than 1.6*RR or not. If the interval is between 1.6*RR and 2.6*RR, it shows that there is likely to be missed detections. Further, if there exists a data in the interval of 0.7*RR to 1.2*RR and with amplitude of 0.5HR (Heart Rate) to 1.5HR interval [22], it can be judged that an R wave is missed in the detection, and the missing R wave would be filled it into the R wave sequence automatically. If the said conditions are not met, it shall be determined whether the R wave is inverted or not. The process of fixing R wave missing-detection is shown in Figure 11. If none of the above cases occurs, it is believed that there is no over-detection or missing detection of the R wave, and then the detection of the next R wave can be conducted.

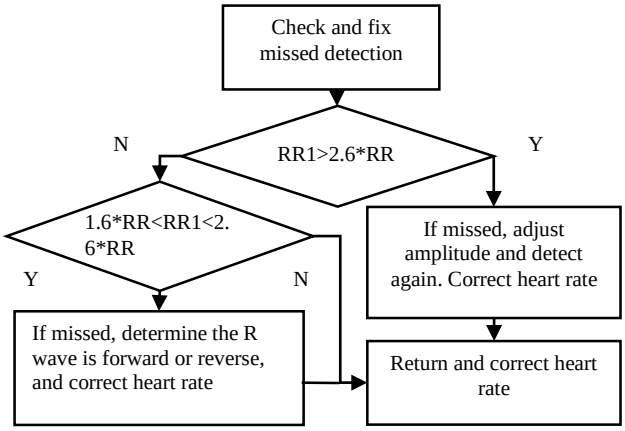

FIGURE 11 The process of R wave detection missed

4 Results

4.1 ALGORITHM VERIFICATION

The multiple groups of the ECG data from the MIT-BIH are adopted to validate the algorithm. After comparing the algorithm test results with the R wave and QRS wave group position provided by the MIT-BIH library [23], it shows that the method can accurately locate the position of the R wave. Tests show that the algorithm can have a detection rate above 99% of normal ECG R waveforms, but the detection rate for the disease ECG waveform (QRS deformation, high P wave and T wave etc.) is over 96%. The average accuracy rate can exceed 97.8%. The following table lists the experimental results respectively. In Table 1, A means atrial premature beat; / means delayed take-off; L means left bundle branch is blocked; a means abnormal atrial premature beat; V means premature ventricular contraction; F means ventricular fusion beat; N means normal; R means right bundle branch is blocked.

TABLE 1 MIT-BIH database library QT signal detection results

MIT-BIH Data record number	Signal Characteristics	False detection rate	Missed detection rate	Accuracy
100	A	0	0	100%
107	/	0	0	100%
108	V	1	3	96%
111	L	0	0	100%
119	VV	0	0	100%
122	N	0	0	100%
201	a	1	0	100%
208	FV	1	1	99%
212	R	0	0	100%
221	V	0	0	100%
234	N	0	0	100%

4.2 HEART RATE DETECTION

The algorithm is adopted to implement the mobile ECG real-time sampling. The mobile ECG detector consists of an integrated precision operational amplifier, a 12 bit digital to analogue converter, a high performance processor and Bluetooth module. It can realize the detection of ECG signals from the fingertips of both hands in the environment of strong background noise and high output impedance. Under the different experimental conditions, the authors have conducted the real-time ECG detection on 12 normal people. The data are as shown in Table 2.

TABLE 2 Mobile ECG monitoring clinical effects

Mobile ECG monitor file name	Visual QRS wave group number	Over detection number	Missed detection number	Error detection rate	Accuracy
201306261321	1992	4	1	2	99.65%
201306261407	1878	1	5	2	99.37%
201306281533	1893	0	2	1	99.84%
201306281607	1589	0	1	2	99.81%
201307011007	1678	3	2	3	99.53%
201307011110	1788	1	2	2	99.72%
201307051310	1684	0	0	3	99.83%
201307051443	1774	3	1	1	99.72%
201307101002	1678	0	1	3	99.77%
201307101120	1567	0	0	0	100%
201401071114	1956	3	0	1	99.58%
201401071207	1556	2	3	1	99.61%
201401071312	1782	1	4	0	99.71%
201401071618	1685	2	3	1	99.64%
201401081110	1856	1	3	2	99.67%
201401081211	1825	2	1	0	99.83%
201401081321	1736	0	0	0	100%
201401081505	1592	2	1	3	99.62%
201401081612	1683	0	1	0	99.94%

The experimental results in Table 2 show that the overall accuracy of the algorithm is above 99%. Experiments show that, in cases of the strong interference, the EMG interference or the conductive body being contacted, the algorithm can accurately calculate the QRS wave. Its detection accuracy is high; its operation speed is fast, and its memory consumption is small, which is suitable for mobile ECG signal processing and application.

5 Conclusion

This paper puts forward the improved detection method based on the difference threshold detection, and has solved the problem of the limitation caused by selecting and fixing the threshold in the traditional differential threshold method. The algorithm is simple, fast in operation, accurate and easy to realize. It can extract and identify the main characteristic parameters of the ECG signals, and lay a solid foundation for the further recognition and diagnosis. The algorithm is tested in the Android intelligent mobile phone, and the test results are satisfactory.

In addition, the system only realizes the lead measuring. The algorithm can be generalized to multiple lead detections, and thus the complete and further detection of the ECG signals can be conducted based on the characteristics of the *P* wave and *T* wave, so as to realize the analysis on the characteristics of more heart diseases.

Abstract

In view of the problem that it is difficult to use only one typical channel to deal with many quantum channels during multi-channel QKD (Quantum Key Distribution), the method of TDM (Time Division Multiplexing) in typical channel is introduced to construct a new CQKD (concurrent QKD) system. Using multi-channel quantum teleportation, every concurrent quantum channel is mapped to a time slot of TDM. The results of case study with EPR (Einstein-Podolsky-Rosen) pairs show that this problem can be solved with the CQKD methods. Moreover, this CQKD scheme also has the advantage of unconditional security, while the QKD bit rates can be improved. It opens a new way to develop large-capacity long-distance quantum secure communications.

Keywords: quantum information security, concurrent quantum key distribution, quantum teleportation, time division multiplexing

1 Introduction

QKD (Quantum Key Distribution) is a newly emerging information security technique to get quantum keys by sending and receiving unknown quantum bits. It is a very important approach to implement quantum information security based on the interdisciplinary fields of quantum cryptology, quantum computation, quantum mechanics, quantum communication and traditional communication. As one of the strongest guarantees to transmit the secure information of unknown quantum bits for quantum keys, it is also becoming the core part of modern cryptology. Since Bennett and Brassard presented the first QKD protocol in 1984 [1], scholars from many countries have dealt with the theories and technologies of QKD, and a lot of important fruits have been achieved. Some valuable research progresses have been achieved in such fields as BB (Bennett-Brassard) 84 protocol [1], Bennett 92 protocol [2], BBM (Bennett-Brassard-Mermin) 92 protocol [3], Ekert 91 protocol [4] and the QKD protocol via quantum teleportation [5-6], etc.

These developments have promoted greatly the QKD techniques to the actual application. Since the quantum cryptogram technology via QKD is a crucial kind of physical cryptography in the world, the QKD systems have a wide range of competitive strategies applications in such fields as military affairs or wars, business, communication, finance, government, etc. Compared with traditional secure communications, the quantum channel capacities of QKD are far smaller, and the corresponding quantum bit rates of QKD are far lower. In recent years, to improve the performances of quantum communication, the multi-channel or parallel QKD techniques were introduced to the fields of quantum information security. For instance, in 2012, Antonio et al [7] combined the WDM (Wavelength Division Multiplexing) and SCM (Subcarrier Multiplexed) techniques to implement microwave photonics parallel QKD. The multiple keys can be delivered, and the final key rate can be increased, which affords the way to multi-QKD in optical fibre networks. In 2013, Zhao et al [8] utilized the forward spectral filtering structure and presented a scheme of parallel QKD, and the shared key generation rate could be increased enhanced several times in theory. Fang et al presented a CV (continuous variable) parallel QKD scheme with the subcarrier multiplexing technique in 2014 [9], and the total secret key rate was increased. In addition, MIMO (Multiple-Input Multiple-Output)-QKD [10-12] and subcarrier multiplexing QKD [9, 13-16] have also been developed to improve quantum channels. These QKD researches above are the early work of multi-channel QKD system with lots of active exploration and significant progresses. These QKD schemes not only remain the advantage of the unconditional security, but also have great capacity of quantum channels. Multi-channel QKD is becoming novel potential footholds of the most powerful quantum cryptography among diverse information security ways, providing much theoretical and technical support for the developments and designs of long-distance large-capacity QKD systems.

Unfortunately, the quantum channels in these multi-channel QKD schemes are considered more, while the indispensable typical channels are not emphasized much. Only one classical channel is not enough to be mapped to every quantum channels. The quantum key transmission in each quantum channel needs the help of the busy essential

[*]***Corresponding author*** e-mail: xiewu588@126.com

classical channel, which are worth improving. In addition, the quantum computations processes of these multi-channel QKD schemes are very complicate lacking unified explicit quantum channel models. As a result, there are some troubles in practical applications and universal generalizations. From the development perspective of the current quantum technologies, the physical mechanisms of this multi-channel QKD system are so intricate that it has been still in the primary stage. The corresponding successful physical experiments of multi-channel QKD system are not many.

Therefore, motivated by ideas of the parallel QKD [7-9], MIMO-QKD [10-12], subcarrier multiplexing QKD [9, 13-16], QKD via quantum teleportation [5, 6], this paper introduces a novel CQKD (Concurrent QKD) system by applying TDM (time division multiplexing) method in the classical channel and concurrent quantum teleportation as multiple quantum channels. Differently from the QKD schemes [7-16], the quantum key string is transmitted currently by dividing the string into several sub-strings with CQKD. At a certain moment, one of concurrent quantum channels is processed, and the time slot resources of TDM typical channel are utilized fully.

This remainder of this paper is arranged as follows. In Section 2, the CQKD system is constructed using quantum entangled states to teleport multiple unknown quantum states, and Section 3 provides the case study of CQKD system by teleporting unknown quantum states of keys with several EPR (Einstein-Podolsky-Rosen) pairs. The performances of the CQKD are analysed in section 4. Finally in section 5, a brief summary is followed.

2 CQKD system using quantum teleportation and TDM

This CQKD system involves the process that legal sender (Alice) and receiver (Bob) send, transmit and obtain quantum keys through multiple quantum channels. The quantum states of the transmission performance by quantum mechanics are used as quantum information carriers. The core approaches to deal with the steps of CQKD are the quantum keys to transmit in every quantum channels with unknown quantum states. The CQKD system can be implemented using the quantum codebook of concurrent quantum key transmissions.

2.1 THE WHOLE SCHEMATIC CONSTRUCTION OF CQKD SYSTEM USING TDM AND QUANTUM TELEPORTATION

CQKD itself is a highly complex quantum system with the transmission of unknown quantum bits via quantum channels. It is also a difficult structural quantum project for physical experiments. From QKD to CQKD system, a potential problem occurs that it is very difficult to arrange and combine the complicate photonic components for the given QKD system, e.g. BS (Beam Splitter), PBS (polarizing beam splitter), BSM (Bell-state measurement), BBO (Beta Barium Borate) crystal, detectors and etc. In contrast to single channel QKD, it is meaningful to construct the CQKD for the unavoidable fact that the quantum components of CQKD are worth exploring.

To take advantage of high key rates of multi-channel quantum communication and explore novel approaches to transmit quantum key information in several quantum channels, the TDM technology is adopted in the classical channel, and a new CQKD system scheme is constructed as shown in Figure 1 by using quantum teleportation as concurrent quantum channels with quantum entangled states.

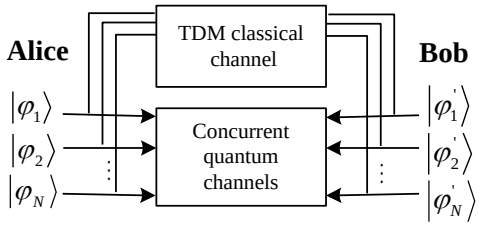

FIGURE 1 the whole schematic construction of CQKD system

Quantum key information of unknown quantum bits is transmitted through concurrent quantum channels. The concurrent processes of QKD can be implemented with N (N is a positive integer) quantum channels. The inputs are the unknown quantum states, while the outputs are the corresponding duplications of these inputs by teleportation with entangled states.

The quantum sources in Figure 1 are discrete with the representations as $|\varphi_1\rangle$, $|\varphi_2\rangle$, … , $|\varphi_N\rangle$, while the destinations are denoted as $|\varphi_1'\rangle$, $|\varphi_2'\rangle$, … , $|\varphi_N'\rangle$. The distances between any two senders (or receivers) are enough without mutual influences or interactions. The number of the senders and receivers of this CQKD system is less than the maximum amount of TDM slots.

2.2 QUANTUM CHANNELS OF CQKD SYSTEM VIA QUANTUM TELEPORTATION

It is feasible to construct the CQKD system via multi-channel quantum teleportation. The characteristics of quantum entangled states with some advantages from microscopic particle world as quantum entanglement resource can be utilized to construct the CQKD system. Therefore, it is necessary to utilize these good properties of quantum entangled particles to design and describe the CQKD system scheme for long-distance key transmission. The concurrent quantum channels can be mapped by diverse quantum entanglement sources, such as EPR states, GHZ (Greenberger-Horne-Zeilinger) states, W states, etc. The transmission distances of quantum bits for quantum key are not limited any more in theory. In quantum channels, no information carriers of quantum key and channels of physical systems for CQKD system interact and influence mutually, and different quantum systems for EPR pairs, GHZ states or W states are often handled differently.

For a CQKD system, the quantum bits are sent and received through multiple quantum channels for a period of time. The channels include TDM typical channel and multiple quantum entangled channels with entangled states. The latter is devised as Figure 2 to illustrate the concurrent processes for QKD with quantum entangled states via concurrent quantum teleportation.

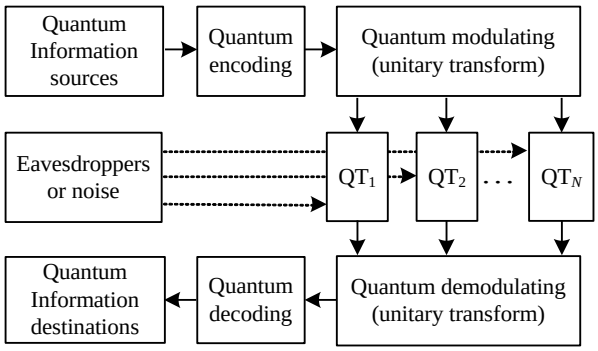

FIGURE 2 Concurrent quantum channels of the CQKD system via quantum teleportation (QT)

The CQKD system in Figure 2 consists of quantum information sources, multiple quantum channels and information destinations. The antennas used in traditional multi-channel communication systems are replaced with several quantum channels where the concurrent quantum bits information is transmitted from the sender to the receiver. The quantum information sources and quantum information destinations are unknown quantum states for quantum keys with the corresponding quantum encoding and quantum decoding processes. The information sources are some quantum bits as the inputs of the CQKD system for Alice, while the outputs are the information destinations as the transmitted results of those quantum bits for Bob. During teleporting of quantum unknown states, the quantum bits of quantum keys in Figure 2 needs modulating and demodulating with unitary transforms.

It is necessary to construct the input-output model of CQKD system using quantum teleportation. Although there are no unified quantitative quantum channel models for the existing multi-channel QKD schemes. Most researchers' schemes for these kinds of QKD system are oriented to their own complex quantum systems, lacking the common formulae of quantum channels. The derivation processes of current theoretical formulae of multi-channel QKD system are exceedingly complicated. It is hard to calculate and compare general quantitative performance indices for QKD. The quantum channels with different quantum carriers are too complicate to describe just like common communications models. Yet, CQKD system emphasizes its multiple inputs and multiple outputs since the inner interacts are too complicate to operate and compute without the unified concept of multi-channel QKD. To abstract the problem of CQKD system with mathematical methods and describe the transmission process of quantum key bits in theory, the CQKD system of N quantum channels is modelled with the abstract input-output relationship between the senders and the receivers.

If none of quantum channels are disturbed by various factors (such as environmental influence, etc.), the general explicit input-output model with quantum entangled states in Figure 1 can be represented as:

$$\begin{bmatrix} |\varphi_1'\rangle \\ |\varphi_2'\rangle \\ \vdots \\ |\varphi_N'\rangle \end{bmatrix} = \begin{bmatrix} \boldsymbol{P}(1|1) & \boldsymbol{P}(1|2) & \cdots & \boldsymbol{P}(1|N) \\ \boldsymbol{P}(2|1) & \boldsymbol{P}(2|2) & \cdots & \boldsymbol{P}(2|N) \\ \vdots & \vdots & \ddots & \vdots \\ \boldsymbol{P}(N|1) & \boldsymbol{P}(N|2) & \cdots & \boldsymbol{P}(N|N) \end{bmatrix} \begin{bmatrix} |\varphi_1\rangle \\ |\varphi_2\rangle \\ \vdots \\ |\varphi_N\rangle \end{bmatrix}, \quad (1)$$

where $\boldsymbol{P}(i|j)$ means the operation $\boldsymbol{P}_{ij}|\varphi_i\rangle \to |\varphi_j'\rangle$ in terms of a series of unitary transforms $(\boldsymbol{P}_{ij})$ $i, j = 1, 2, \ldots, N$.

If there is no disturbs in each ideal quantum channel with some independent irrelevant discrete quantum entanglement sources, the input-output model can be simplified as follows:

$$\begin{bmatrix} |\varphi_1'\rangle \\ |\varphi_2'\rangle \\ \vdots \\ |\varphi_N'\rangle \end{bmatrix} = \begin{bmatrix} \boldsymbol{P}(1|1) & 0 & \cdots & 0 \\ 0 & \boldsymbol{P}(2|2) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \boldsymbol{P}(N|N) \end{bmatrix} \begin{bmatrix} |\varphi_1\rangle \\ |\varphi_2\rangle \\ \vdots \\ |\varphi_N\rangle \end{bmatrix}. \quad (2)$$

In a certain quantum channel, $|\varphi_j'\rangle$ is the input unknown quantum bit which carries the quantum key information to the output $|\varphi_j'\rangle$. The input-output relations of multiple quantum channels are determined by the variable $\boldsymbol{P}(i|j)$. According to quantum mechanics, $\boldsymbol{P}(i|j)$ are the results of a series of unitary transforms which are implemented in physics, which depends on the physical characteristics of quantum channels for CQKD.

2.3 EAVESDROPPING ANALYSIS OF CQKD SYSTEM IN QUANTUM CHANNELS AND TDM CLASSICAL CHANNEL

For the CQKD system, eavesdropping detection is essential in every quantum channels. The error quantum bits for CQKD can be from eavesdroppers and environment noise, which need to be distinguished. Although the quantum key transmission processes for CQKD are affected by environmental noise. For instance, the quantum key transmission in free space may be interfered by high buildings, mountains, dust, atmosphere and noise, etc. Yet concurrent quantum teleportation of unknown quantum bits in free space are affected little by environmental factors. The quantum bits information during teleporting in multiple quantum channels almost has little decay if the quantum entanglement sources are not affected. Potential noise in quantum channels for entangled states differs in free space or optical fibre. So, eavesdropping analysis for CQKD is crucial to obtain correct quantum bits of quantum keys.

Alice often transmits much quantum key information to Bob, and Bob then detects and determines the correctness of the received quantum bits. Alice and Bob need to identify the input and output parameters of quantum states in concurrent quantum channels. They also have to check whether the quantum key bits in concurrent quantum channels are influenced by the eavesdroppers during transmitting the keys. According to the theory of quantum signal detection, the behaviours of eavesdropping can be detectable in quantum systems. For a CQKD system, any eavesdropping in quantum channels will leave traces, providing the chance to detect the error quantum bits information. The quantum keys during concurrent quantum teleportation may be affected by potential eavesdroppers. According to the no-cloning quantum principle, none of them can copy accurately unknown quantum states which are adopted as information sources of this CQKD system. So, whenever the quantum channels between Alice and the Bob for the CQKD system are affected or eavesdropped on, Eve can be detected. In addition, data correction and privacy enhancing process are also required to realize CQKD.

3 Case study of CQKD system by concurrent quantum teleportation with EPR pairs and TDM

The quantum computing processes of a CQKD system need much work, and it is difficult to abstract the unified multiple channel models just like multi-channel quantum communications and the typical communication schemes [7-16]. It is also hard to achieve and solve universal general computational formulas and variables.

In order to simplify and derive the complex computation processes for the CQKD system, the quantum teleportation with EPR pairs are taken as an example of concurrent quantum channels to research the CQKD system according to Equation (2). So, for simply, it is supposed that there are no interacts in multiple quantum channels. Such quantum entanglement states as EPR states are taken as the transmission medium of the unknown quantum state to deal with quantum key bits by concurrent quantum teleportation just for the CQKD system.

3.1 SCHEME OF CQKD SYSTEM VIA CONCURRENT QUANTUM TELEPORTATION WITH EPR PAIRS

For the implementation for the detailed multiple quantum transmission of quantum keys with unknown quantum states, the antennae used in traditional multi-channel communications are replaced with multiple independent purified EPR pairs by the corresponding relationships between the quantum channels and quantum entangled states. These EPR pairs are mapped into the quantum channels for the CQKD system. The classical channel used in the quantum teleportation is divided into many time slots with the way from classical communications (such as a telephone), and the CQKD system scheme with EPR pairs is constructed and shown in Figure 3. Alice and Bob identify, negotiate and determine the unknown quantum bits of QKD through TDM typical channel.

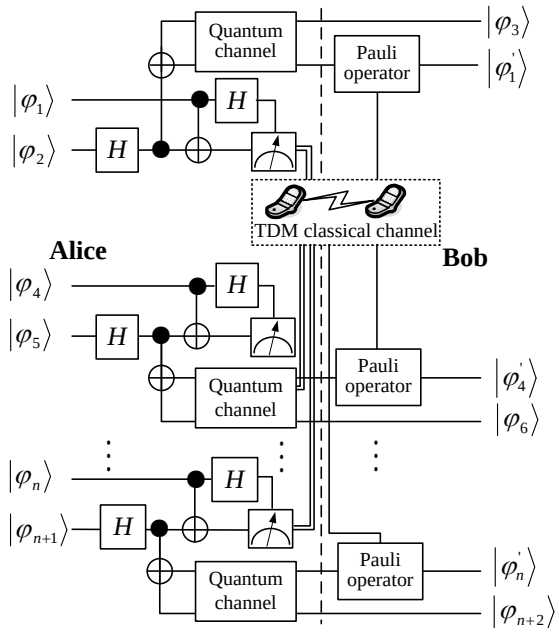

FIGURE 3 CQKD system by quantum teleportation with EPR pairs

H is a Hadamard gate, and $\oplus$ is a control-NOT gate. The quantum bits carrying quantum key information to be transmitted are denoted as the input unknown quantum particles $|\varphi_1\rangle$, $|\varphi_4\rangle$, …, $|\varphi_n\rangle$, while $|\varphi_1'\rangle$, $|\varphi_4'\rangle$, …, $|\varphi_n'\rangle$ is the corresponding outputs.

The EPR pairs in concurrent quantum channels are represented as $|\varphi_2\rangle$ and $|\varphi_3\rangle$, $|\varphi_5\rangle$ and $|\varphi_6\rangle$,… ,$|\varphi_{n+1}\rangle$ and $|\varphi_{n+2}\rangle$, which are from corresponding purified homotype independent quantum entangled sources. n is a positive integer.

Alice and Bob can implement remote quantum correlations with quantum entanglement states. To construct concurrent quantum channels, they can select purified entanglement photon sources to produce EPR pairs with polarization photos as the multiple quantum channels for the CQKD system.

3.2 PROCESSES OF CQKD SYSTEM VIA QUANTUM TELEPORTATION WITH EPR PAIRS

For simplification, three quantum channels for quantum communication are taken as examples to describe the principle of a CQKD system scheme to obtain the input-output transformations relations during the concurrent quantum key transmissions. The process of this scheme via concurrent teleportation with EPR pairs can be divided into the following steps as the main contents of the protocol [5, 6] for the CQKD system.

Firstly, unknown quantum states and EPR entangled pairs are prepared for the CQKD system. Assuming some

independent purified quantum entangled photon sources are prepared in three quantum channels, and these EPR pairs are transmitted to Alice and Bob in the opposite direction respectively. As a result, Alice has quantum particles $|\varphi_2\rangle$, $|\varphi_5\rangle$ and $|\varphi_8\rangle$, while Bob holds the responding quantum particles $|\varphi_3\rangle$ and $|\varphi_6\rangle$, $|\varphi_9\rangle$. The initial quantum states of these EPR pairs are supposed as the following Bell states:

$$|\beta_{00}\rangle_{23} = |\Phi^+\rangle_{23} = (|00\rangle_{23} + |11\rangle_{23})/\sqrt{2}, \tag{3}$$

$$|\beta_{01}\rangle_{56} = |\Psi^+\rangle_{56} = (|01\rangle_{56} + |10\rangle_{56})/\sqrt{2}, \tag{4}$$

$$|\beta_{10}\rangle_{89} = |\Phi^-\rangle_{89} = (|00\rangle_{89} - |11\rangle_{89})/\sqrt{2}, \tag{5}$$

where 23, 56 and 89 are denoted as three pairs of quantum entangled particles respectively.

The quantum key information is contained in three unknown quantum particles $|\phi_1\rangle$, $|\phi_4\rangle$ and $|\phi_7\rangle$ which initial states are represented as:

$$|\varphi_1\rangle = a|0_1\rangle + b|1_1\rangle, \tag{6}$$

$$|\varphi_4\rangle = c|0_4\rangle + d|1_4\rangle, \tag{7}$$

$$|\varphi_7\rangle = e|0_7\rangle + f|1_7\rangle, \tag{8}$$

where *a*, *b*, *c*, *d*, *e* and *f* are complex coefficients.

Theoretically, Alice and Bob are entangled through any quantum channels no matter how far away they are. So, the CQKD through quantum teleportation in every sub-channel is ready and practicable, and the quantum bit information is prepared to be transmitted and gained with a certain probability via quantum entangled states.

Secondly, unknown quantum states through EPR states are teleported and duplicated across three concurrent quantum channels. Alice and Bob teleport unknown quantum bit information for quantum keys in each quantum channel during different time slots of the TDM classical channel. The classical channel is divided into several discrete periodic time slots, so that Alice and Bob can observe and measure quantum entangled states to determine legal quantum bits for the CQKD system with the same physical connection of different TDM time slots.

During these time slots, Alice chooses unknown particles (such as $|\phi_1\rangle$, $|\phi_4\rangle$ and $|\phi_7\rangle$) to perform the joint measurement operations with the corresponding EPR pairs $|\phi_2\rangle$ and $|\phi_3\rangle$, $|\phi_5\rangle$ and $|\phi_6\rangle$, $|\phi_8\rangle$ and $|\phi_9\rangle$ respectively, that is, the tensor products are performed:

$$\begin{bmatrix} |\varphi_{123}\rangle \\ |\varphi_{456}\rangle \\ |\varphi_{789}\rangle \end{bmatrix} = \begin{bmatrix} (a|0_1\rangle + b|1_1\rangle) \otimes (|00\rangle_{23} + |11\rangle_{23})/\sqrt{2} \\ (c|0_4\rangle + d|1_4\rangle) \otimes (|01\rangle_{56} + |10\rangle_{56})/\sqrt{2} \\ (e|0_7\rangle + f|1_7\rangle) \otimes (|00\rangle_{89} - |11\rangle_{89})/\sqrt{2} \end{bmatrix}. \tag{9}$$

According to quantum mechanics, these joint quantum measurement operations will result in the instant collapse changes of each EPR pairs during the corresponding time slot, and the quantum entanglement between Alice and Bob are disentangled, while $|\phi_1\rangle$ and $|\phi_2\rangle$, $|\phi_4\rangle$ and $|\phi_5\rangle$, $|\phi_7\rangle$ and $|\phi_8\rangle$ are entangled separately. So, these quantum information of $|\phi_3\rangle$, $|\phi_6\rangle$ and $|\phi_9\rangle$ for Bob need separating, and the results are the following.

$$\begin{bmatrix} |\varphi_{123}\rangle \\ |\varphi_{456}\rangle \\ |\varphi_{789}\rangle \end{bmatrix} = \frac{1}{\sqrt{2}} \begin{bmatrix} (a|00\rangle_{12} + b|10\rangle_{12})|0\rangle_3 + (a|01\rangle_{12} + b|11\rangle_{12})|1\rangle_3 \\ (c|01\rangle_{45} + d|11\rangle_{45})|0\rangle_6 + (c|00\rangle_{45} + d|10\rangle_{45})|1\rangle_6 \\ (e|00\rangle_{78} + f|10\rangle_{78})|0\rangle_9 - (e|01\rangle_{78} + f|11\rangle_{78})|1\rangle_9 \end{bmatrix}. \tag{10}$$

Using the method of dual items, we have:

$$\begin{bmatrix} |\varphi_{123}\rangle \\ |\varphi_{456}\rangle \\ |\varphi_{789}\rangle \end{bmatrix} = \frac{1}{2\sqrt{2}} \begin{bmatrix} \begin{pmatrix} (a(|00\rangle_{12} + |11\rangle_{12}) + b(|01\rangle_{12} + |10\rangle_{12}) + a(|00\rangle_{12} - |11\rangle_{12}) + b(-|01\rangle_{12} + |10\rangle_{12}))|0\rangle_3 \\ +(b(|00\rangle_{12} + |11\rangle_{12}) + a(|01\rangle_{12} + |10\rangle_{12}) + b(-|00\rangle_{12} + |11\rangle_{12}) + a(|01\rangle_{12} - |10\rangle_{12}))|1\rangle_3 \end{pmatrix} \\ \begin{pmatrix} (d(|00\rangle_{45} + |11\rangle_{45}) + c(|01\rangle_{45} + |10\rangle_{45}) + d(-|00\rangle_{45} + |11\rangle_{45}) + c(|01\rangle_{45} - |10\rangle_{45}))|0\rangle_6 \\ +(c(|00\rangle_{45} + |11\rangle_{45}) + d(|01\rangle_{45} + |10\rangle_{45}) + c(|00\rangle_{45} - |11\rangle_{45}) + d(-|01\rangle_{45} + |10\rangle_{45}))|1\rangle_6 \end{pmatrix} \\ \begin{pmatrix} (e(|00\rangle_{78} + |11\rangle_{78}) + f(|01\rangle_{78} + |10\rangle_{78}) + e(|00\rangle_{78} - |11\rangle_{78}) + f(-|01\rangle_{78} + |10\rangle_{78}))|0\rangle_9 \\ -f(|00\rangle_{78} + |11\rangle_{78}) - e(|01\rangle_{78} + |10\rangle_{78}) + f(|00\rangle_{78} - |11\rangle_{78}) + e(-|01\rangle_{78} + |10\rangle_{78}))|1\rangle_9 \end{pmatrix} \end{bmatrix}. \tag{11}$$

Four Bell states are used for Equation (11), and then we can get:

$$\begin{bmatrix} |\varphi_{123}\rangle \\ |\varphi_{456}\rangle \\ |\varphi_{789}\rangle \end{bmatrix} = \frac{1}{2}\begin{bmatrix} \left(|\beta_{00}\rangle_{12}(a|0\rangle_3 + b|1\rangle_3) + |\beta_{01}\rangle_{12}(b|0\rangle_3 + a|1\rangle_3) + |\beta_{10}\rangle_{12}(a|0\rangle_3 - b|1\rangle_3) + |\beta_{11}\rangle_{12}(-b|0\rangle_3 + a|1\rangle_3)\right) \\ \left(|\beta_{00}\rangle_{45}(d|0\rangle_6 + c|1\rangle_6) + |\beta_{01}\rangle_{45}(c|0\rangle_6 + d|1\rangle_6) + |\beta_{10}\rangle_{45}(-d|0\rangle_6 + c|1\rangle_6) + |\beta_{11}\rangle_{45}(c|0\rangle_6 - d|1\rangle_6)\right) \\ \left((e|\beta_{00}\rangle_{78} + f|\beta_{01}\rangle_{78} + e|\beta_{10}\rangle_{78} - f|\beta_{11}\rangle_{78})|0\rangle_9 + (-f|\beta_{00}\rangle_{78} - e|\beta_{01}\rangle_{78} + f|\beta_{10}\rangle_{78} - e|\beta_{11}\rangle_{78})|1\rangle_9\right) \end{bmatrix}. \quad (12)$$

The Equations (6)-(8) of the unknown particles are substituted into Equation (12), and the three-channel CQKD system via teleportation is expressed as Equation (13):

$$\begin{bmatrix} |\varphi_{123}\rangle \\ |\varphi_{456}\rangle \\ |\varphi_{789}\rangle \end{bmatrix} = \frac{1}{2}\begin{bmatrix} \left(|\beta_{00}\rangle_{12}\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix}|\varphi_3\rangle + |\beta_{01}\rangle_{12}\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}|\varphi_3\rangle + |\beta_{10}\rangle_{12}\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}|\varphi_3\rangle + |\beta_{11}\rangle_{12}\begin{bmatrix}0 & -1\\ 1 & 0\end{bmatrix}|\varphi_3\rangle\right) \\ \left(|\beta_{00}\rangle_{45}\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}|\varphi_6\rangle + |\beta_{01}\rangle_{45}\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix}|\varphi_6\rangle + |\beta_{10}\rangle_{45}\begin{bmatrix}0 & -1\\ 1 & 0\end{bmatrix}|\varphi_6\rangle + |\beta_{11}\rangle_{45}\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}|\varphi_6\rangle\right) \\ \left(|\beta_{00}\rangle_{78}\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}|\varphi_9\rangle + |\beta_{01}\rangle_{78}\begin{bmatrix}0 & 1\\ -1 & 0\end{bmatrix}|\varphi_9\rangle + |\beta_{10}\rangle_{78}\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix}|\varphi_9\rangle + |\beta_{11}\rangle_{78}\begin{bmatrix}0 & -1\\ -1 & 0\end{bmatrix}|\varphi_9\rangle\right) \end{bmatrix}. \quad (13)$$

Using inverse unitary transform, Bob can duplicates the unknown quantum states $|\phi_1'\rangle$, $|\phi_4'\rangle$, $|\phi_7'\rangle$ according to Equation (13), and $\boldsymbol{P}(i|j)$ in Equation (2) can be implemented. Consequently, the concurrent unknown quantum bits for quantum keys are transmitted from Alice to Bob.

Thirdly, quantum keys are obtained from these teleported unknown quantum states for CQKD system. Through the typical channel, Alice and Bob compare and find out those transmitted quantum bits where the measurement bases are the same during the time slot of the classical channel. They choose effective unknown quantum bits by identical measurement bases to establish the codebook for QKD. The QKD protocols [5, 6] of quantum teleportation can be adopted, and Eve can be checked whether they exist in each quantum channel or not. When the quantum channel is not eavesdropped on, the quantum bits for the corresponding QKD are legal, or the transmitted quantum bits have to be cancelled. By transmitting constantly unknown quantum states, the quantum bit string can be gained and determine whether the transmission process is effective to carry out the collection of quantum key information. After quantum error correcting code and privacy amplification, Alice and Bob combine the effective unknown quantum bits from concurrent quantum channel to build the codebook for the quantum key of the CQKD system.

Thus, results of three-channel CQKD system by concurrent quantum teleportation with EPR pairs are obtained as Equation (13). It is worth mentioning that the CQKD systems of four or more concurrent quantum channels are similar through those quantum channels of EPR pairs and TDM classical channel. The input-output relationship in Equation (13) is also in accordance with the quantum channel model of Equation (2), and the former can be generalized to the CQKD of N quantum channels under the ideal condition of no environmental impacts.

4 Discussion

Similarly, with the existing multi-channel QKD schemes, the CQKD system in this paper also has unconditional security according to the Heisenberg uncertainty principle and the quantum no-cloning theorem. Moreover, this CQKD scheme in our work brings two other advantages.

Firstly, QKD can be implemented through concurrent quantum channels in the CQKD system by TDM methods. Every quantum channel can be mapped with a time slots of classical channel for Alice and Bob to exchange the information of quantum states and measure bases. From the concurrent quantum channels of the instance with EPR pairs, not only the input-output models of are simpler than the multi-channel QKD schemes, but also the concurrent quantum teleportation process of unknown quantum bits can be implemented. So, the CQKD system has the crucial factors of TDM time slots for successful quantum keys, and the time slot resource is utilized fully.

Secondly, this CQKD system improves the performance of QKD bit rates. For the QKD scheme of only one typical channel, the error (from eavesdroppers) probability during transmitting unknown quantum bits is denoted as p_e, then the ideal maximum successful probability of QKD for Alice and Bob is $1-p_e$ at a time. $0 \le p_e \le 1$. In contrast, for this CQKD system with TDM typical channel, Alice can transmit the quantum key information by teleporting multiple unknown quantum states to Bob when one or more of concurrent quantum channels are available. For instance, for a CQKD system of N irrelevant quantum channels, if the classical channel is divided into N time slots, then the ideal maximum successful probability of QKD is $1-p_e^N$ at a time. So, the

maximum probability for Alice and Bob to implement successful transmissions of unknown quantum bits for CQKD rises greatly with the increasing number of concurrent quantum channel. So, the high QKD bit rates for the CQKD system can be obtained by TDM technology, which was not be guaranteed with only one classical channel for every quantum channels before.

5 Conclusion

In this paper, the problem of only one typical channel to multiple quantum channels for multi-channel QKD schemes has been solved by the CQKD system. The TDM tool is used to ensure the one-to-one mapping of a time slot in classical channel and each quantum channel. The case study of EPR pairs illustrate that the model of CQKD system can be constructed via concurrent quantum teleportation. Performance analyses show that the CQKD system not only has the advantage of unconditional security, but also the QKD bit rates can be enhanced in contrast with the single-channel QKD. With the development of quantum information security, the model of CQKD system can be generalized with GHZ states, W states, etc. This CQKD scheme opens a novel way to develop large-capacity long-distance quantum secure communications.

Abstract

The integrable coupling of the WKI hierarchy is obtained by the perturbation approach. With the help of a higher dimensional loop algebra, the coupling integrable couplings of the WKI hierarchy are obtained, respectively. Their Hamiltonian structures are worked out by employing the component-trace identities and variational identity.

Keywords: coupling integrable couplings, component-trace identities, perturbation equation

1 Introduction

The notion on integrable couplings was introduced when study of Virasoro symmetric algebras [1, 2]. To find as many new integrable systems and their integrable couplings as possible and to elucidate in depth their algebraic and geometric properties are of both theoretical and practical value. During the past few years, some interesting integrable couplings and associated properties of some known interesting integrable hierarchies, such as the AKNS hierarchy, the KN hierarchy, the Burger hierarchy, etc. were obtained [3-13] In order to get Hamiltonian structures of integrable couplings, Guo and Zhang proposed the quadratic-form identity [14]. After this, Ma and Chen [15, 16] built the variational identity and generalized the quadratic-form identity and obtained some integrable couplings and their Hamiltonian structures. Recently, Ma and Zhang [17] proposed the notion on component-trace identities. They are very effective to construct the Hamiltonian structure of the perturbation equation. In Ref. [18], Ma and Gao proposed the notion called coupling integrable couplings of the nonlinear Schr¨odinger equation and associated symmetry properties, etc. Based on this, Zhang and Tam [19] constructed a few higher dimensional Lie algebras to obtain the coupling integrable couplings of the AKNS hierarchy and the KN hierarchy.

In the paper, we first give the first-order perturbation equation of the WKI hierarchy and its Hamiltonian structure is worked out by employing the component-trace identities. Then we use the way presented in Ref. [18-19] to investigate the coupling integrable couplings of the WKI hierarchy. In Refs. [18-19], the author didn't obtain the Hamiltonian structure of the coupling integrable couplings, while in the paper the Hamiltonian structures of the coupling integrable couplings of the WKI hierarchy will be worked out by using the variational identity.

2 The perturbation equation of the WKI hierarchy and its Hamiltonian structure

Yao and Zhang [20] utilized Tu scheme to obtain the multi-component WKI hierarchy. In this section, we take the perturbation way to deduce the integrable coupling of the WKI hierarchy and employ the component-trace identities to generate its Hamiltonian structure.

Consider the isospectral problem of the WKI hierarchy

$$\varphi_x = U\varphi, U = \begin{pmatrix} -i\lambda & u_1\lambda \\ u_2\lambda & i\lambda \end{pmatrix}, \varphi = \begin{pmatrix} \varphi_1 \\ \varphi_2 \end{pmatrix}, \qquad (1)$$

where u_1, u_2 are potentials and λ is the spectral parameter. By means of constructing a proper time evolution

$$\varphi_{t_n} = V^{[n]}\varphi, V^{[n]} = \sum_{m=0}^{n} \begin{pmatrix} \lambda a_m & b_{mx} + i\lambda u_1 a_m \\ c_{mx} + i\lambda u_2 a_m & -\lambda a_m \end{pmatrix} \lambda^{n-m}, \qquad (2)$$

and using the zero-curvature equation, we have the WKI hierarchy:

$$u_{t_n} = \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}_{t_n} = \begin{pmatrix} 0 & -\partial^2 \\ \partial^2 & 0 \end{pmatrix} L^n \begin{pmatrix} \frac{u_2}{\sqrt{1-u_1u_2}} \\ \frac{u_1}{\sqrt{1-u_1u_2}} \end{pmatrix} = JL^n \begin{pmatrix} \frac{u_2}{\sqrt{1-u_1u_2}} \\ \frac{u_1}{\sqrt{1-u_1u_2}} \end{pmatrix}, \qquad (3)$$

**Corresponding author* e-mail: 343927567@qq.com

where:

$$L=\begin{pmatrix} -\frac{i}{2}\partial-\frac{i}{4}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 & \frac{i}{4}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^2 \\ -\frac{i}{4}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 & \frac{i}{2}\partial+\frac{i}{4}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^2 \end{pmatrix}. \tag{4}$$

Accordingly, when $n=0$, we can get the WKI equation. By using the race identity, we can obtain the Hamiltonian structure of the WKI hierarchy

$$u_{t_n}=J\frac{\delta H_{n-1}}{\delta u}, \tag{5}$$

where $H_{n-1}=\int\frac{a_{n-1}+u_2b_{n-1}-u_1c_{n-1}}{n-1}dx.$

Next, we will construct a integrable coupling of the WKI hierarchy by the perturbation approach and its Hamiltonian structure by the component-trace identities.

Let us take a matrix Lie algebra g consisting of the following matrices:

$$A=\begin{bmatrix} A_0 & A_1 & \cdots & \cdots & A_N \\ & A_0 & A_1 & & \vdots \\ & & \ddots & \ddots & \vdots \\ & & & A_0 & A_1 \\ 0 & & & & A_0 \end{bmatrix}, \tag{6}$$

where $A_i,\ 0\le i\le N,$ are square matrices of the same order. For convenience, we rewrite an element of the Lie algebra g as a vector of matrices: $A=(A_0,A_1,\cdots,A_N)$, where the components $A_i,1\le i\le N$, are defined by:

$$A_i=\frac{1}{i!}\frac{\partial^i}{\partial\varepsilon^i}|_{\varepsilon=0}\ A(\hat{u}_N),\hat{u}_N=u+u+\sum_{i=1}^{N}\varepsilon^i\eta_i,1\le i\le N. \tag{7}$$

The enlarged zero-curvature equation by perturbation

$$\hat{U}_{Nt}-\hat{V}_{Nt}+[\hat{U}_N,\hat{V}_N]=0,$$

where $\hat{U}_N=u+\sum_{i=0}^{N}\varepsilon^i\eta_i$, $\hat{V}_N=V+\sum_{i=0}^{N}\varepsilon^i\eta_i,1\le i\le N$ give rise to the perturbation equation of the Nth order:

$$\hat{\eta}_{Nt}=\hat{K}_N(\hat{\eta}_N)=(K^T(u),\frac{1}{1!}\frac{\partial}{\partial\varepsilon}|_{\varepsilon=0}\ K^T(\hat{u}_N),\cdots,$$
$$\frac{1}{N!}\frac{\partial^N}{\partial\varepsilon^N}|_{\varepsilon=0}\ K^T(\hat{u}_N))^T,$$

where the column vector $\hat{\eta}_N$ of dependent variables is $\hat{\eta}_N=(u^T,\eta_1^T,\cdots,\eta_N^T)$. In what follows, we focus on the perturbation equation of the first order. We consider an isospectral problem as follows:

$$\bar{U}(\bar{u},\lambda)=\hat{U}_1=\begin{bmatrix} U_0 & U_1 \\ 0 & U_0 \end{bmatrix},\bar{V}(\bar{v},\lambda)=\hat{V}_1=\begin{bmatrix} V_0 & V_1 \\ 0 & V_0 \end{bmatrix}, \tag{8}$$

where U_0 and V_0 are defined by Equations (1) and (2), U_1 and V_1 are showed as follows:

$$U_1=\frac{1}{1!}\frac{\partial}{\partial\varepsilon}|_{\varepsilon=0}\ U(\hat{u}_1)=\frac{\partial}{\partial\varepsilon}|_{\varepsilon=0}\begin{bmatrix} -i\lambda & u_1\lambda+\varepsilon\lambda u_3 \\ u_2\lambda+\varepsilon\lambda u_4 & i\lambda \end{bmatrix}= \tag{9}$$
$$\begin{bmatrix} 0 & \lambda u_3 \\ \lambda u_4 & 0 \end{bmatrix},$$

$$V_1=\frac{\partial}{\partial\varepsilon}|_{\varepsilon=0}\begin{bmatrix} \lambda a+\varepsilon\lambda d & B \\ C & -\lambda a-\varepsilon\lambda d \end{bmatrix}= \tag{10}$$
$$\begin{bmatrix} \lambda d & f_x+i\lambda u_4a+i\lambda u_1d \\ g_x+i\lambda u_5a+i\lambda u_2d & -\lambda d \end{bmatrix},$$

where:

$$B=b_x+i\lambda u_1a+\varepsilon(f_x+i\lambda u_4a+i\lambda u_1d),$$
$$C=c_x+i\lambda u_2a+\varepsilon(g_x+i\lambda u_5a+i\lambda u_2d).$$

The enlarged stationary zero-curvature equation $\hat{V}_x=[\hat{U},\hat{V}]$ equivalently yields:

$$\begin{cases} V_x=[U,V], \\ V_{1x}=[U,V_1]+[U_1,V]. \end{cases} \tag{11}$$

A direct calculation leads to:

$$\begin{cases} a_{mx} = u_1 c_{mx} - u_2 b_{mx}, \\ i(u_1 a_{m+1})_x + b_{mxx} = -2ib_{m+1x}, \\ i(u_2 a_{m+1})_x + c_{mxx} = 2ic_{m+1x}, \\ d_{mx} = u_3 c_{mx} + u_1 f_{mx} - u_2 e_{mx} - u_4 b_{mx}, \\ f_{mxx} + i(u_1 d_{m+1})_x + i(u_3 a_{m+1})_x = -2if_{m+1x}, \\ g_{mxx} + i(u_2 d_{m+1})_x + i(u_4 a_{m+1})_x = 2ig_{m+1x}, \\ a_0 = \alpha_1, b_0 = \alpha_2, c_0 = \alpha_3, d_0 = \alpha_4, g_0 = \alpha_5, f_0 = \alpha_6, \\ a_1 = \dfrac{2}{\sqrt{1-u_1u_2}}, b_1 = \dfrac{-u_1}{\sqrt{1-u_1u_2}}, c_1 = \dfrac{u_2}{\sqrt{1-u_1u_2}}, \\ d_1 = \dfrac{1}{\sqrt{1-u_1u_2}} + \dfrac{u_1u_4 + u_2u_3}{(1-u_1u_2)^{3/2}}, \\ f_1 = -\dfrac{u_1}{2\sqrt{1-u_1u_2}} - \dfrac{u_1(u_1u_4 + u_2u_3)}{2(1-u_1u_2)^{3/2}} - \dfrac{u_3}{\sqrt{1-u_1u_2}}, \\ g_1 = \dfrac{u_2}{2\sqrt{1-u_1u_2}} + \dfrac{u_2(u_1u_4 + u_2u_3)}{2(1-u_1u_2)^{3/2}} + \dfrac{u_4}{\sqrt{1-u_1u_2}}. \end{cases} \tag{12}$$

From the recursion relation in Equation (12), we have a recursive formula for determining f_n, g_n:

$$\begin{bmatrix} g_n \\ -f_n \end{bmatrix} = L\begin{bmatrix} g_{n-1} \\ -f_{n-1} \end{bmatrix} + L_1\begin{bmatrix} c_{n-1} \\ -b_{n-1} \end{bmatrix} = L\begin{bmatrix} g_{n-1} \\ -f_{n-1} \end{bmatrix} + \begin{bmatrix} L_{11} & L_{12} \\ L_{13} & L_{14} \end{bmatrix}\begin{bmatrix} c_{n-1} \\ -b_{n-1} \end{bmatrix}, \tag{13}$$

where:

$$L_{11} = -\frac{i}{4}\frac{u_4}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 - \frac{i}{8}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^{-1}\Big(\frac{u_1}{\sqrt{1-u_1u_2}}\partial\frac{u_4}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_2}{\sqrt{1-u_1u_2}}\partial\frac{u_3}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_3}{\sqrt{1-u_1u_2}}\partial\frac{u_2}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_4}{\sqrt{1-u_1u_2}}\partial\frac{u_1}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 + 2i\frac{u_3}{\sqrt{1-u_1u_2}}\partial^2\Big),$$

$$L_{12} = \frac{i}{4}\frac{u_4}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^2 + \frac{i}{8}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^{-1}\Big(\frac{u_1}{\sqrt{1-u_1u_2}}\partial\frac{u_4}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_2}{\sqrt{1-u_1u_2}}\partial\frac{u_3}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_3}{\sqrt{1-u_1u_2}}\partial\frac{u_2}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_3}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_4}{\sqrt{1-u_1u_2}}\partial\frac{u_1}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^2 + 2i\frac{u_4}{\sqrt{1-u_1u_2}}\partial^2\Big),$$

$$L_{13} = -\frac{i}{4}\frac{u_3}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 - \frac{i}{8}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^{-1}\Big(\frac{u_1}{\sqrt{1-u_1u_2}}\partial\frac{u_4}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_2}{\sqrt{1-u_1u_2}}\partial\frac{u_3}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_3}{\sqrt{1-u_1u_2}}\partial\frac{u_2}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_4}{\sqrt{1-u_1u_2}}\partial\frac{u_1}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^2 + 2i\frac{u_3}{\sqrt{1-u_1u_2}}\partial^2\Big),$$

$$L_{14} = \frac{i}{4}\frac{u_3}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^2 + \frac{i}{8}\frac{u_1}{\sqrt{1-u_1u_2}}\partial^{-1}\Big(\frac{u_1}{\sqrt{1-u_1u_2}}\partial\frac{u_4}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_2}{\sqrt{1-u_1u_2}}\partial\frac{u_3}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_3}{\sqrt{1-u_1u_2}}\partial\frac{u_2}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_3}{\sqrt{1-u_1u_2}}\partial^2 + \frac{u_4}{\sqrt{1-u_1u_2}}\partial\frac{u_1}{\sqrt{1-u_1u_2}}\partial^{-1}\frac{u_2}{\sqrt{1-u_1u_2}}\partial^2 + 2i\frac{u_4}{\sqrt{1-u_1u_2}}\partial^2\Big).$$

Then the enlarged zero-curvature equation $\hat{U}_{t_n} - \hat{V}_x^{[n]} + [\hat{U}, \hat{V}^{[n]}] = 0$ yields the hierarchy of the first-order perturbation equation:

$$\bar{U}_{t_n} = (u_1, u_2, u_3, u_4)_{t_n}^T = \begin{bmatrix} 0 & J \\ J & J_1 \end{bmatrix} \left(g_{n-1}, -f_{n-1}, c_{n-1}, -b_{n-1}{}^T \right), \quad (14)$$

where

$$J_1 = \frac{1}{1!} \frac{\partial}{\partial \varepsilon} |_{\varepsilon=0} \; J(\hat{u}_1) = \begin{bmatrix} 0 & -\partial^2 \\ \partial^2 & 0 \end{bmatrix}. \quad (15)$$

Hence, we can get the following integrable couplings of Equation (3) as follows:

$$\begin{cases} u_{1t} = \left(\dfrac{iu_1}{\sqrt{1-u_1u_2}} \right)_{xx}, \\ u_{2t} = \left(-\dfrac{iu_2}{\sqrt{1-u_1u_2}} \right)_{xx}, \\ u_{3t} = \left(-\dfrac{u_1}{2\sqrt{1-u_1u_2}} - \dfrac{u_1(u_1u_4+u_2u_3)}{2(1-u_1u_2)^{\frac{3}{2}}} - \dfrac{u_3}{\sqrt{1-u_1u_2}} \right)_{xx}, \\ u_{4t} = \left(\dfrac{u_2}{2\sqrt{1-u_1u_2}} + \dfrac{u_2(u_1u_4+u_2u_3)}{2(1-u_1u_2)^{\frac{3}{2}}} + \dfrac{u_4}{\sqrt{1-u_1u_2}} \right)_{xx}. \end{cases} \quad (16)$$

In order to generate the Hamiltonian structure of the first-order perturbation equation of the WKI hierarchy, we introduce the following theorem:

Theorem 1 [17] Let g be a matrix Lie algebra consisting of block matrices defined by Equation (6). For a given spectral matrix $U = U(u,\lambda) = (U_0, U_1, \cdots, U_N) \in g$, we have the variational identity:

$$\begin{aligned} &\frac{\delta}{\delta u} \int \sum_{k=0}^{N} \alpha_k \operatorname{tr}\left(\sum_{i+j=k} V_i \frac{\partial U_j}{\partial \lambda} \right) dx = \\ &\lambda^{-\gamma} \frac{\partial}{\partial \lambda} \lambda^{\gamma} \sum_{k=0}^{N} \alpha_k \operatorname{tr}\left(\sum_{i+j=k} V_i \frac{\partial U_j}{\partial u} \right), \end{aligned} \quad (17)$$

where $V = V(v,\lambda) = (V_0, V_1, \cdots, V_N) \in g$ satisfies the zero-curvature equation, all α_k's are arbitrary constants with $\alpha_N \neq 0$ and γ is the constant determined by $\gamma = -\frac{1}{2} \frac{d}{d\lambda} ln |< V, V >|$. This variational identity Equation (17) is called the component-trace identity. For a general integer N, we have:

$$\frac{\delta}{\delta u} \int \operatorname{tr}\left(\sum_{i+j=N} V_i \frac{\partial U_j}{\partial \lambda} \right) dx = \lambda^{-\gamma} \frac{\partial}{\partial \lambda} \lambda^{\gamma} \operatorname{tr}\left(\sum_{i+j=N} V_i \frac{\partial U_j}{\partial u} \right), \quad (18)$$

which is called the last-component-trace identity. Then, the generating function of Hamiltonian functions for the perturbation equation of N-th order is computed as follows: $\hat{H}(\hat{\eta}_N) = \operatorname{tr}\left(\sum_{i+j=N} V_i \frac{\partial U_j}{\partial \lambda} \right)$, where $\hat{\eta}_N = (u^T, \eta_1^T, \cdots, \eta_N^T)^T$. This implies that the last-component-trace identity provides the generation function of Hamiltonian functions for the perturbation equation. Then, basing on the generating function of Hamiltonian functions for the original equation $H_g(u) = \operatorname{tr}\left(V \frac{\partial U}{\partial \lambda} \right)$, we can get the generating function of Hamiltonian functions for the perturbation equations of N-th order as follows:

$$\begin{aligned} &\hat{H}_{g,N}(\hat{\eta}_N) = \frac{1}{N!} \frac{\partial^N}{\partial \varepsilon^N} |_{\varepsilon=0} \; H_g(\hat{u}_N) = \\ &\operatorname{tr}\left(\frac{1}{N!} \frac{\partial^N}{\partial \varepsilon^N} |_{\varepsilon=0} \; V(\hat{u}_N) \frac{\partial}{\partial \lambda} U(\hat{u}_N) \right) = \\ &\operatorname{tr}\left(\frac{1}{N!} \sum_{i+j=N} \binom{i}{N} \frac{\partial^i}{\partial \varepsilon^i} |_{\varepsilon=0} \; V(\hat{u}_N) \frac{\partial^j}{\partial \varepsilon^j} |_{\varepsilon=0} \; \frac{\partial}{\partial \lambda} U(\hat{u}_N) \right) = \\ &\operatorname{tr}\left(\sum_{i+j=N} \frac{1}{i!} \frac{\partial^i}{\partial \varepsilon^i} |_{\varepsilon=0} \; V(\hat{u}_N) \frac{\partial}{\partial \lambda} (\frac{1}{j!} \frac{\partial^j}{\partial \varepsilon^j} |_{\varepsilon=0} \; U(\hat{u}_N) \right) = \\ &\operatorname{tr}\left(\sum_{i+j=N} V_i \frac{\partial U_j}{\partial \lambda} \right). \end{aligned} \quad (19)$$

By using the above results, a direct calculation reads

$$\begin{aligned} &\operatorname{tr}\left(\sum_{i+j=1} V_i \frac{\partial U_j}{\partial \lambda} \right) = \operatorname{tr}\left(V_1 \frac{\partial U_0}{\partial \lambda} + V_0 \frac{\partial U_1}{\partial \lambda} \right) = \\ &(-2i\lambda d - 2iu_2 f + 2iu_1 g - 2iu_4 b + 2iu_3 c), \end{aligned} \quad (20)$$

$$\begin{aligned} &\operatorname{tr}(V_1 \frac{\partial U_0}{\partial u_1}) = 2i\lambda g, \operatorname{tr}\left(V_1 \frac{\partial U_0}{\partial u_2} \right) = -2i\lambda f, \\ &\operatorname{tr}\left(V_0 \frac{\partial U_1}{\partial u_3} \right) = 2i\lambda c, \operatorname{tr}\left(V_0 \frac{\partial U_1}{\partial u_4} \right) = -2i\lambda b. \end{aligned} \quad (21)$$

Basing on the last-component-trace identities, we have

$$\begin{aligned} &\frac{\delta}{\delta u} \int (-2id_{n-1} - 2iu_2 f_{n-1} + 2iu_1 g_{n-1} - \\ &2iu_4 b_{n-1} + 2iu_3 c_{n-1}) dx = 2i(2+\gamma-n)[g, -f, c, -b]^T. \end{aligned} \quad (22)$$

Take $n = 2$ in above equation gives $\gamma = -1$. Thus, the Hamiltonian structure of the perturbation equation of the WKI hierarchy is derived as follows:

$$\hat{U}_{t_n} = (u_1, u_2, u_3, u_4)_{t_n}^T = \begin{bmatrix} 0 & J \\ J & J_1 \end{bmatrix} \frac{\delta H_{n-1}}{\delta u}, \quad (23)$$

where:

$$H_{n-1} = \frac{1}{n-1} \int (d_{n_1} + u_2 f_{n-1} - u_1 g_{n-1} + u_4 b_{n-1} - u_3 c_{n-1}) dx.$$

3 The coupling integrable couplings of the WKI hierarchy and its Hamiltonian structure

The coupling of the WKI hierarchy is given in the above. In the section, we will construct the coupling integrable couplings by following the way in Ref. [18], which is introduced as follows.

Given two integrable couplings of the integrable equation $u_t = K(u)$:

$$\bar{u}_{1,t} = \bar{K}_1(\bar{u}_1) = \begin{bmatrix} K(u) \\ S(u,v) \end{bmatrix}, \bar{u}_1 = \begin{bmatrix} u \\ v \end{bmatrix}, \tag{24}$$

$$\bar{u}_{2,t} = \bar{K}_2(\bar{u}_2) = \begin{bmatrix} K(u) \\ T(u,v) \end{bmatrix}, \bar{u}_2 = \begin{bmatrix} u \\ w \end{bmatrix}, \tag{25}$$

a new bigger system is formed as follows:

$$\hat{u}_t = \hat{K}(\hat{u}) = \begin{bmatrix} K(u) \\ S(u,v) \\ T(u,v) \end{bmatrix}, \hat{u} = \begin{bmatrix} u \\ v \\ w \end{bmatrix}. \tag{26}$$

We call Equation (26) coupling integrable couplings of Equations (24) and (25).

First, we will construct a 9-dimensional vector-Lie algebra and its corresponding loop algebra. Consider a vector space [18]:

$$R^9 = span\{a = (a_1, \cdots, a_9)^T, a_i \in R, i = 1, 2, \cdots, 9\}.$$

For $\forall a = (a_1, \cdots, a_9)^T$, $b = (b_1, \cdots, b_9)^T$, define a commutation operation:

$$\begin{aligned}[a,b] = &(a_2b_3 - a_3b_2, 2(a_1b_2 - a_2b_1), 2(a_3b_1 - a_1b_3), a_2b_6 - a_6b_2 + a_5b_3 - a_3b_5, 2(a_1b_5 - a_5b_1 + a_4b_2 - a_2b_4),\\ &2(a_6b_1 - a_1b_6 + a_3b_4 - a_4b_3), a_2b_9 - a_9b_2 + a_8b_3 - a_3b_8 + a_8b_9 - a_9b_8, 2(a_1b_8 - a_8b_1 + a_7b_2 - a_2b_7 + a_7b_8 - a_8b_7),\\ &2(a_9b_1 - a_1b_9 + a_3b_7 - a_7b_3 + a_9b_7 - a_7b_9))^T\end{aligned} \tag{27}$$

It is verified that R^9 is a Lie algebra if equipped with Equation (27). Take a basis of R^9 as follows:

$$e_i = (e_{i1}, \cdots, e_{i9})^T, e_{ij} = \begin{cases} 1, i = j, \\ 0, i \neq j, 1 \leq i, j \leq 9. \end{cases} \tag{28}$$

A loop algebra $\tilde{R}^9$ corresponding to the Lie algebra R^9 is defined as:

$$\tilde{R}^9 = span\{e_i(n)\}_{i=1}^9, e_i(n) = e_i\lambda^n, [e_i(m) - e_j(n)] = [e_i, e_j]\lambda^{m+n}, 1 \leq i, j \leq 9, m, n \in Z. \tag{29}$$

By employing the loop algebra $\tilde{R}^9$, we consider the following Lax pair:

$$\begin{cases} U = -ie_1(1) + u_1e_2(1) + u_2e_3(1) + u_3e_5(1) + u_3e_6(1) + u_5e_8(1) + u_6e_9(1), \\ V = \sum_{m=0}^{\infty}[a_me_1(1-m) + iu_1a_me_2(1-m) + b_{mx}e_2(-m) + iu_2a_me_3(1-m) + c_{mx}e_3(-m)n + \\ d_me_4(1-m) + f_{mx}e_5(-m) + i(u_3a_m + u_1d_m)e_5(1-m) + g_{mx}e_6(-m) + i(u_4a_m + u_2d_m)e_6(1-m) + . \\ h_me_7(1-m) + p_{mx}e_8(-m) + i(u_5a_m + u_5h_m + u_1h_m)e_8(1-m) + q_{mx}e_9(-m)n + \\ i(u_6a_m + u_6h_m + u_2h_m)e_9(1-m)] \end{cases}$$

A solution to $V_x = [U, V]$ exhibits that:

$$\begin{cases} a_{mx} = u_1c_{mx} - u_2b_{mx}, \\ i(u_1a_{m+1})_x + b_{mxx} = -2ib_{m+1x}, \\ i(u_2a_{m+1})_x + c_{mxx} = 2ic_{m+1x}, \\ d_{mx} = u_1g_{mx} - u_2f_{mx} + u_3c_{mx} - u_4b_{mx}, \\ i(u_3a_{m+1} + u_1d_{m+1})_x + f_{mxx} = -2if_{m+1x}, \\ i(u_4a_{m+1} + u_2d_{m+1})_x + g_{mxx} = 2ig_{m+1x}, \\ h_{mx} = u_1q_{mx} - u_2p_{mx} + u_5c_{mx} - u_6b_{mx} + u_5q_{mx} - u_6p_{mx}, \\ i(u_5a_{m+1} + u_5h_{m+1} + u_1h_{m+1})_x + p_{mxx} = -2ip_{m+1x}, \\ i(u_6a_{m+1} + u_6h_{m+1} + u_2h_{m+1})_x + q_{mxx} = 2iq_{m+1x}. \end{cases} \tag{30}$$

Note:

$$V_+^{(n)} = \sum_{m=0}^{n}[a_m e_1(n+1-m) + iu_1 a_m e_2(n+1-m) + b_{mx} e_2(n-m) + iu_2 a_m e_3(n+1-m) +$$
$$c_{mx} e_3(n-m) + d_m e_4(n+1-m) + f_{mx} e_5(n-m) + i(u_3 a_m + u_1 d_m) e_5(n+1-m) + g_{mx} e_6(n-m) +$$
$$i(u_4 a_m + u_2 d_m) e_6(n+1-m) + h_m e_7(n+1-m) + p_{mx} e_8(n-m) + i(u_5 a_m + u_5 h_m + u_1 h_m) e_8(n+1-m) +$$
$$q_{mx} e_9(n-m) + i(u_6 a_m + u_6 h_m + u_2 h_m) e_9(n+1-m)].$$

Set $V_-^{(n)} = \lambda^n V - V_+^{(n)}$, we have:

$$-V_{+x}^{(n)} + [U, V_+^{(n)}] = -\lambda b_{n-1xx} e_2(0) - \lambda c_{n-1xx} e_3(0) - \lambda f_{n-1xx} e_5(0) - \lambda g_{n-1xx} e_6(0) - \lambda p_{n-1xx} e_8(0) - \lambda q_{n-1xx} e_9(0). \quad (31)$$

Therefore, the zero-curvature equation

$$U_t - V_x^{(n)} + [U, V^{(n)}] = 0, \quad (32)$$

admits the following bigger integrable system:

$$U_t = \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ u_5 \\ u_6 \end{pmatrix}_t = \begin{pmatrix} 0 & 0 & 0 & -\partial^2 & 0 & 0 \\ 0 & 0 & \partial^2 & 0 & 0 & 0 \\ 0 & -\partial^2 & 0 & 0 & 0 & -\partial^2 \\ \partial^2 & 0 & 0 & 0 & \partial^2 & 0 \\ 0 & 0 & 0 & -\partial^2 & 0 & -\partial^2 \\ 0 & 0 & \partial^2 & 0 & \partial^2 & 0 \end{pmatrix} \begin{pmatrix} c_{n-1} + g_{n-1} + q_{n-1} \\ -b_{n-1} - f_{n-1} - p_{n-1} \\ c_{n-1} \\ -b_{n-1} \\ c_{n-1} + q_{n-1} \\ -b_{n-1} - p_{n-1} \end{pmatrix}. \quad (33)$$

Substituting $u_5 = u_6 = 0$ in Equation (33) reduces to the Equation (14), which is an integrable coupling of the WKI hierarchy; when taking $u_3 = u_4 = 0$ in Equation (33) reduces to another integrable coupling of the WKI hierarchy. So we call Equation (33) the coupling integrable couplings of the WKI hierarchy.

In order to deduce to the Hamiltonian structure of Equation (33), we rewrite Equation (30) as follows:

$$[a, b] = a^T R(b), \quad (34)$$

where:

$$R(b) = \begin{pmatrix} 0 & 2b_2 & -2b_3 & 0 & 2b_5 & -2b_6 0 & 2b_8 & -2b_9 & 0 \\ b_3 & -2b_1 & 0 & b_6 & -2b_4 & 0 & b_9 & -2b_7 & 0 \\ -b_2 & 0 & 2b_1 & -b_5 & 0 & 2b_4 & -b_8 & 0 & 2b_7 \\ 0 & 0 & 0 & 0 & 2b_2 & -2b_3 & 0 & 0 & 0 \\ 0 & 0 & 0 & b_3 & -2b_1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -b_2 & 0 & 2b_1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2(b_2 + b_8) & -2(b_3 + b_9) \\ 0 & 0 & 0 & 0 & 0 & 0 & b_3 + b_9 & -2(b_1 + b_7) & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -(b_2 + b_8) & 0 & 2(b_1 + b_7) \end{pmatrix}.$$

Solving the matrix equation for the constant matrix F:

$$R(b)F = -(R(b)F)^T, F^T = F,$$

$$F=\begin{pmatrix}2&0&0&2&0&0&2&0&0\\0&0&1&0&0&1&0&0&1\\0&1&0&0&1&0&0&1&0\\2&0&0&0&0&0&0&0&0\\0&0&1&0&0&0&0&0&0\\0&1&0&0&0&0&0&0&0\\2&0&0&0&0&0&2&0&0\\0&0&1&0&0&0&0&0&1\\0&1&0&0&0&0&0&1&0\end{pmatrix}. \tag{35}$$

Then in terms of F, define a linear functional: $\{a,b\}=a^TFb$. Rewrite the Lax pair as follows:

$$\begin{cases}U=(-i\lambda,\lambda u_1,\lambda u_2,0,\lambda u_3,\lambda u_4,0,\lambda u_5,\lambda u_6)^T,\\ V=(\lambda a,b_x+i\lambda u_1a,c_x+i\lambda u_2a,\lambda d,f_x+i\lambda(u_3a+u_1d),g_x+i\lambda(u_4a+u_2d),\lambda h,\\ p_x+i\lambda(u_5a+u_5h+u_1h),q_x+i\lambda(u_6a+u_5h+u_1h))^T.\end{cases} \tag{36}$$

By using the above linear functional, we have:

$$\left\{V,\frac{\partial U}{\partial\lambda}\right\}=-2i(a+d+h)+2iu_1(c+g+q)-2iu_2(b+f+p)+2iu_3c-2iu_4b+2iu_5(c+q)-2iu_6(b+p),$$

$$\left\{V,\frac{\partial U}{\partial u_1}\right\}=2i\lambda(c+g+q),\left\{V,\frac{\partial U}{\partial u_2}\right\}=-2i\lambda(b+f+p),\left\{V,\frac{\partial U}{\partial u_3}\right\}=2i\lambda c,\left\{V,\frac{\partial U}{\partial u_4}\right\}=-2i\lambda b,$$

$$\left\{V,\frac{\partial U}{\partial u_5}\right\}=2i\lambda(c+q),\left\{V,\frac{\partial U}{\partial u_6}\right\}=-2i\lambda(b+p).$$

According the variational identity, we have

$$\frac{\delta}{\delta u}\int(-2i(a+d+h)+2iu_1(c+g+q)-2iu_2(b+f+p)+2iu_3c-2iu_4b+2iu_5(c+q)-2iu_6(b+p))dx=$$

$$\lambda^{-\gamma}\frac{\partial}{\partial\lambda}\lambda^{\gamma}(2i\lambda(c+g+q),-2i\lambda(b+f+p),2i\lambda c,-2i\lambda b,2i\lambda(c+q),-2i\lambda(b+p))^T.$$

Comparing the coefficients of λ^{-n+1} yields

$$\frac{\delta}{\delta u}\int(-2i(a_{n-1}+d_{n-1}+h_{n-1})+2iu_1(c_{n-1}+g_{n-1}+q_{n-1})-2iu_2(b_{n-1}+f_{n-1}+p_{n-1})+2iu_3c_{n-1}-$$

$$2iu_4b_{n-1}+2iu_5(c_{n-1}+q_{n-1})-2iu_6(b_{n-1}+p_{n-1}))dx=2i(2+\gamma-n)\begin{pmatrix}-c_{n-1}-g_{n-1}\\b_{n-1}+f_{n-1}\\-c_{n-1}\\b_{n-1}\end{pmatrix}.$$

Taking $n=2$ in above equation gives $\gamma=-1$.

Hence, the coupling integrable couplings of WKI hierarchy Equation (33) can be written as a Hamiltonian form:

$$U_t = \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ u_5 \\ u_6 \end{pmatrix}_t = \begin{pmatrix} 0 & 0 & 0 & -\partial^2 & 0 & 0 \\ 0 & 0 & \partial^2 & 0 & 0 & 0 \\ 0 & -\partial^2 & 0 & 0 & 0 & -\partial^2 \\ \partial^2 & 0 & 0 & 0 & \partial^2 & 0 \\ 0 & 0 & 0 & -\partial^2 & 0 & -\partial^2 \\ 0 & 0 & \partial^2 & 0 & \partial^2 & 0 \end{pmatrix} \begin{pmatrix} c_{n-1} + g_{n-1} + q_{n-1} \\ -b_{n-1} - f_{n-1} - p_{n-1} \\ c_{n-1} \\ -b_{n-1} \\ c_{n-1} + q_{n-1} \\ -b_{n-1} - p_{n-1} \end{pmatrix} = J \frac{\delta H_{n-1}}{\delta u}, \tag{37}$$

where

$$H_{n-1} = \frac{1}{n-1} \int ((a_{n-1} + d_{n-1} + h_{n-1}) - u_1(c_{n-1} + g_{n-1} + q_{n-1}) + u_2(b_{n-1} + f_{n-1} + p_{n-1}) -$$
$$u_3 c_{n-1} + u_4 b_{n-1} - u_5(c_{n-1} + q_{n-1}) + u_6(b_{n-1} + p_{n-1}))dx,$$

J is a Hamiltonian operator.

4 Conclusions

In Ref.[19], the coupling integrable couplings of KN and AKNS hierarchy are obtained, but their Hamiltonian structures aren't given. In the paper, however, the integrable coupling of WKI hierarchy is obtained by the perturbation approach and its Hamiltonian structure is given by using the component-trace identities. Meanwhile, basing on a 9-dimensional Lie algebra, we discuss the coupling integrable couplings of the WKI hierarchy and obtain its Hamiltonian structure by the variational identity.

In the future, we will discuss the perturbation equation and coupling integrable couplings of other hierarchies and their Hamiltonian structures.

Abstract

Java programs may suffer from serious memory leak bugs. To resolve these bugs, various leak diagnosing and even fixing techniques have been proposed. However, in literature, there is very few work, which focuses on memory leak testing. Without revealing leak phenomenon by testing in advance, even excellent leak diagnosing and fixing techniques can be hard to work. In software testing, unit testing is a technique to avoid faults at early stage of software development. This paper proposes an automated unit-level memory leak testing approach to find potential leak bugs in Java methods. It firstly identifies the methods with high leaking risks. Then, strengthened unit tests are generated accordingly to check whether those risky modules can really cause leaks. Cases studies show that our method could be valuable for real programs.

Keywords: Java, memory leak, unit testing, test generation

1 Introduction

Even though with garbage collection supports, memory leak still remains a problem for Java programs. The leaks usually occur when a Java program unnecessarily maintains references to objects that are no longer required. Memory Leaks may degrade runtime performance and even lead to crashes due to out of memory exceptions.

To resolve these leak bugs, various techniques have been proposed [1-7], and there are also a lot of supporting tools [11, 12]. The previous work mainly focuses on leak diagnosing and fixing, which find out the causes of leaks after memory leak phenomenon occur [1-7] and fix the leaking code [8-10]. However, in literature, there is very few work concerning on how to discover those potential memory leak phenomenon. Without a discovered leak phenomena, in most cases, it will be hard to trigger a diagnosis process and eliminate the leak error.

Software testing is a promising technique to discover potential failures. But approaches for testing memory leaks are hard to see. In this paper, we present an automated testing method to find memory leak phenomenon at unit level. The approach firstly finds out the leak risky methods and then generates normal unit tests for them. We then strengthen these unit tests to detect memory leaks. By testing leaks at unit-level, memory leaks can be avoided as early as possible in the whole lifecycle of software.

In the work, we classify the leak risky modules into three categories: modules directly creating and leaking large number of objects, modules that accumulate new objects created by themselves and may lead to leaks after repeated calls to them, modules that absorb their arguments and may lead to leaks after repeated calls. These modules can be identified with dependency, points-to, and escape information.

For those leak risky modules, we firstly use some existing approaches [13] to generate normal unit tests as start points. Then, these tests are augmented with large input data, repeated calls, and other techniques to strengthen the memory usage and monitor mechanisms to observe the leak. Finally, we can get the leak revealing unit tests. We studied usage of our approach on several already found memory leak bugs from JDK bug database. The results show that the approach is effective in revealing real leaking modules. This indicates that it can be valuable for practical uses.

2 Technique backgrounds

2.1 DEPENDENCE ANALYSIS

Dependency between program statements can be categorized into two types: control dependence caused by control structures in the program and data dependence caused by reads and writes of memory locations [14].

We can get control and data dependences between nodes in control flow graph via dependence analysis [14]. In this paper, we need to know whether a loop's control condition is influenced by method parameters. By dependence analysis, we can get the data dependence relationships between program nodes, and then judge whether the loop's condition node directly or indirectly depends on method parameter by checking whether there is a path from the method parameter to the condition node. If there exist such kinds of paths, it indicates that the loop's control condition is potentially influenced by method's parameters.

2.2 POINTER AND ESCAPE ANALYSIS

Pointer analysis determines all the possible memory locations that a pointer may point to at runtime. In Java, a pointer is a variable of reference type and what it points to is an object on the heap [15].

This paper uses a context-insensitive algorithm implemented in Soot [17] to do the pointer analysis.

*Corresponding author e-mail ljhong307@163.com

Escape analysis tracks the lifetime of objects and determine whether it may escape from some given scopes. An object can be directly created by a new instruction or indirectly created by a wrapper method of some new instruction. It is considered to possibly escape from the scope of a method if a reference to the object is returned from the method, or if a reference to the object is assigned to a field of an external object [16].

This paper extends the escape analysis presented in [16] to do risky method analysis. In addition to that in [16], the extended analysis also adds loops as the analysed scopes. We firstly identify all objects created in the loops. Then, a constraint system is built according to the statements in the relevant method following the constraint-based approach in [16]. Finally, we can determine whether the objects in the loop may escape loop scope by the extended escape analysis.

3 Leak risky modules: a classification

As discussed in the introduction part, the leak risky modules can be classified into three categories. We will introduce them in more detail in this section.

3.1 MODULES DIRECTLY LEAKING OBJECTS

Modules directly creating and leaking objects have the following characteristics:

1) Creating objects repeatedly in loops inside the module;

2) The number of rounds that these loops can execute is unbounded and determined by the module inputs;

3) The objects created by the loops cannot be released on time. Such modules may directly consume large memory when the inputs are large. The memory requirement may be caused by improper object allocation and release mechanism and is unnecessary. It may cause memory leaks.

```
class Test1{
1    static Vector cache = new Vector();
2    public void foo(int n){
3       for( int i = 1; i < n; i ++ ){
4          Data d = new Data();
5          cache.add(d);
6          doSth(d);
7       }
8    }
}
```

FIGURE 1 An example of modules directly leaking objects

Figure 1 demonstrates an example for the modules that directly creating and leaking objects. In Figure 1, method foo may directly cause memory leaks. In foo, there is a loop which creates new objects inside it. The execution rounds of the loop are unbounded and determined by the method's input parameter *n*. During each round, object d created in the loop is added into an external cache. The cached objects are not freed on time. Given a very large input, the method may directly consume too much memory and lead to out of memory error.

3.2 MODULES ACCUMULATING NEWLY CREATED OBJECTS

Modules that accumulate newly created objects and can lead to memory leak usually have the following characteristics:

1) Creating objects inside the module;

2) The objects escape from module's scope and get stored through a way other than the method return value and parameters. It may unconsciously consume large memory after repeated calls and thereby cause memory leaks.

```
class Test2{
1    static Vector cache = new Vector();
2    public Data bar(){
3       Data d = new Data();
4       cache.add(d);
5       return d;
6    }
  }
```

FIGURE 2 An example of modules accumulating newly created objects

Figure 2 demonstrates an example for the modules of the second category. In Figure 2, method bar creates a new object d and accumulates it into container cache. If the cache is not cleaned on time, after a large number of calls to the bar() method, there will be too many Data objects stored in the container cache, which may cause memory leaks.

3.3 MODULES ABSORBING ARGUMENT OBJECTS

A module that absorbs argument objects and can lead to memory leak usually has at least one of its parameter objects potentially escaping out of the module's scope through a way other than the method return value and parameters. The escaped parameter object can be long-termly absorbed by the module. It may lead to memory leaks after many calls to the module.

```
class Test3{
1    static Vector cache = new Vector();
2    public void zar(Data d){
3       cache.add(d);
4       doSth(d);
5    }
  }
```

FIGURE 3 An example of modules absorbing argument objects

Figure 3 shows an example for the modules of this category. In Figure 3, a reference type parameter is passed into method zar in line 2. In line 3, parameter d is absorbed by method zar to an external cache. The method may unconsciously absorb too many parameter objects after repeated calls, which may causes leaks and finally lead to out of memory error.

4 Identifying Leak Risky Modules

This section presents the methods for identifying three kinds of leak risky modules, respectively.

4.1 IDENTIFYING MODULES DIRECTLY LEAKING OBJECTS

We firstly search the loops that create new objects in a method on the control flow graph. Then whether these loops' control conditions can be influenced by the method inputs are determined. Finally, we use pointer and escape analyses to determine whether the new objects' created in those loops can live beyond the loop scope. If the condition of a loop that creates new objects is potentially influenced by the method inputs and the created objects can live beyond the loop scope, it indicates that the module has a high risk in directly leaking huge memory.

Algorithm 1: Identifying modules that directly leaking objects

```
Input: m: Method
Output: Boolean
   Dependence analysis;
pointer and escape analyses;
let L_m be the set of all loops in m
foreach l∈L_m do
     if hasNewInstruction(l) then
      if isInputDependent(l) then
if isNewObjectEscape(l) then
return true;
end
        end
    end
  end
return false;
```

The algorithm is shown in Algorithm 1. It returns a Boolean value for each input method m to show whether the method may cause leaks. The algorithm firstly collects Lm, the set of all loops in m, by loop analysis. Then, each loop l is processed. We firstly check whether loop l can introduce new objects by predicate hasNewInstruction(l). The new objects include the ones created directly by new instructions and the ones created by other callee methods. Then we determine whether loop l is input dependent on the method's parameters by predicate isInputDependent(l). Finally, we use predicate isNewObjectEscape(l) to check whether the newly introduced objects may escape from the loop scope. When all the above conditions are satisfied, it indicates that method m is a leak risky module.

For isInputDependent(l), we firstly obtain the dependence node corresponding to the loop condition. Starting from this node, we traverse the program dependence graph to get a set of nodes that the loop condition node depends on. If the set contains any node corresponding to the method's parameter, it indicates loop l's condition depends on method inputs.

For isNewObjectEscape(l), we firstly check whether the objects created in the loop escape from the method scope by existing escape analysis. If they escape, of course the objects escape from the loop scope. Otherwise, we will check whether the objects created by the loop may escape from the loop scope by our extended escape analysis.

4.2 IDENTIFYING MODULES ACCUMULATING NEWLY CREATED OBJECTS

We firstly obtain all the objects newly created in a module. Then, pointer and escape analysis are used to determine lifetime of these objects and whether they may escape from the method scope via internal leak sources and thereby be accumulated.

The algorithm is shown in Algorithm 2. It returns a Boolean value for each input method m to show whether the method may cause leaks after repeated calls. We firstly obtain a collection of internal escape sources excluding the return value and parameters by function getInternalLeakSources(). If method m accumulates its created objects, the new objects will escape from these sources. With these special escape sources, we do escape analysis for the method. Having got the escape information, we check each newly created object in the method, and finally determine whether there is any object escaping from the method scope by predicate isEscape(o). If such objects exist, the method may potentially cause memory leaks.

Algorithm 2: Identifying modules that accumulating newly created objects

```
Input: m:method
Output: Boolean
   escape_sources := getInternalLeakSources();
   pointer and escape analysis;
   newObjects := getAllNewObjects();
   foreach o∈newObjects do
     if isEscape(o) then
        return true;
    end
end
return false;
```

4.3 IDENTIFYING MODULES ABSORBING ARGUMENT OBJECTS

We firstly check whether a module's parameters are reference types and regard the reference typed parameters as newly created objects in the modules. Then, pointer and escape analyses can be used to find out the lifetime of these objects and determine whether they may escape from method scope.

Algorithm 3: Identifying modules that absorbing argument objects

```
Input: m:method
Output: Boolean
     newObjects := markParamsAsNewObject (m);
pointer and escape analyses;
foreach o∈newObjects then
if isEscape(o) then
return true;
          end
    end
return false;
```

The algorithm is shown in Algorithm 3. It is similar to Algorithm 2. We firstly set method's reference parameters as newly created objects by markParamsAsNewObject(m). With these special newObjects, we do pointer and escape analyses for the method. Based on the escape information,

we check each newly created object in the method to determine whether there is any object escaping from method scope by predicate isEscape(o). If such objects exist, the method is a leak risky module.

5 Creating unit tests

For the leak risky modules, the users can pick up the modules that they believe should not cause continuously memory growth to do the unit testing.

Our unit test generation approach firstly uses some existing methods to generate normal unit tests. Then, we use enlarged input data, repeated method calls, and other techniques to strengthen their memory use, and insert memory monitor mechanisms to observe the leaking behaviors. Finally a collection of unit tests for memory leak testing purpose can be obtained.

The approach creates JUnit format test cases. In the current implementation, we use a tool named CodeProAnalytix [13] to generate normal JUnit test cases for the risky modules. The augmenting methods are discussed below.

5.1 CREATING UNIT TESTS FOR MODULES DIRECTLY LEAKING OBJECTS

For the modules that could directly cause leaks, we use large input data to strengthen memory use and insert memory growth assertions to determine whether the leaks can really occur.

```
public class UnitTest1 {
1       @Before
2       public void setUp() throws Exception {
3       }
4       @Test
5       public void testFoo(){
6           Test1 test = new Test1();
7           int n = MemoryTester.LARGE_INT;
8           long memoryBefore = MemoryTester.getUsed-
Memory();
9           test.foo(n);
10                  long memoryAfter =
MemoryTester.getUsedMemory();
11      MemoryTester.assertMemoryGrowth(memoryBefore,
memoryAfter, NO_SIGNIFICANT_GROWTH);
12  }
}
```

FIGURE 4 Unit testing with large input data and memory assertions

Figure 4 shows a unit test generated for the example in Figure 1. The normal unit test generated by the existing tools only contains the creation of Test1 object and a call to its method foo. In the normal unit test, it passes a random initial value to the tested method. To test memory leaks, in statement 7, we set a large input data MemoryTester.LARGE_INT for the tested method foo to strengthen memory use. Our approach currently supports several different types of large data, including the primitive types, such as int, long, float, and so on, and some object types, such as String. For the primitive types, we just use some previously defined huge value. For String type, we generate a pool of large strings and randomly select one of them. We obtain the memory consummation before and after foo by calls to method MemoryTester.getUsedMemory() and determine whether the method cause leaks by assertion MemoryTester.assertMemoryGrowth(memoryBefore, memoryAfter, NO_SIGNIFICANT_GROWTH). The assertion checks whether the memory growth is in the normal range. It uses a predefined value NO_SIGNIFICANT_GROWTH to set the allowed growth range. The constant means only small memory growth is allowed. If the memory grows over the allowed value, we consider the risky method really causes memory leaks. With the above strengthen, the unit test can validate whether the leak risky method actually lead to a noticeable leak.

5.2 CREATING UNIT TESTS FOR MODULES ACCUMULATING NEWLY CREATED OBJECTS

For the second kind of leak risky modules, we use repeated method calls to strengthen the memory usage, and insert memory growth assertions to check whether the leak risky modules can really lead to leaks.

```
public class UnitTest2 {
1       @Before
2       public void setUp() throws Exception {
3       }
4       @Test
5       public void testBar(){
6           Test2 test = new Test2 ();
7           long memoryBefore = MemoryTester.getUsedMemory();
8           for(int i=0;i<MemoryTester.LARGE_LOOPNUM;i++){
9               test.bar();
10          }
11          long memoryAfter = MemoryTester.getUsedMemory();
12          MemoryTester.assertMemoryGrowth(memoryBefore,
memoryAfter, NO_SIGNIFICANT_GROWTH);
13      }
}
```

FIGURE 5 Unit testing with repeated method calls and memory assertions

Figure 5 shows a unit test for the example in Figure 2. We use the existing tools to generate the normal unit test. In the normal unit test, there only have the creation of Test2 object and a call to method bar. We generate the test code on the base of the normal unit test. Statement 8 puts method bar into a loop and sets a large number for the loop to strengthen memory use. Then, the memory growth assertions checks whether the memory growth is normal. If the growth is abnormal, it indicates the leak risky method may be leaking the memory.

5.3 CREATING UNIT TESTS FOR MODULES ABSORBING ARGUMENT OBJECTS

We use a weak reference based mechanism to determine whether the third kind of leak risky modules can cause problems.

```
public class UnitTest3{
1   @Before
2   public void setUp() throws Exception {
  }
  @Test
public void testZar(){
   Test3 test = new Test3();
   Object obj = new Data();
   WeakReference<Object>  ref= MemoryTester.prepareArgu-
ment(obj);
   test.zar(obj);
   obj = null;
   MemoryTester.assertArgumentNotLeaked (ref);
}
}
```

FIGURE 6 Unit testing with weak reference based leak detection mechanism

Figure 6 shows a unit test generated for the example in Figure 3. The paper firstly generates a normal unit test only containing the instantiation of Test3, the creation of an argument object, and a call to its method zar. Then, it generates strengthened unit test based on weak reference mechanism. A weak reference will be garbage collected when its referee is disconnected from other references. By checking whether a weak reference is broken, we can know whether an object is hold by other references. In the unit test, statement 8 uses MemoryTester.prepareArgument (objs) to add a weak reference ref to method zar's argument obj. It sets reference obj to null in statement 10. After that, if the argument obj is not absorbed by method zar, then the weak reference should be broken after some round of garbage collections, since there is no other reference to the argument object. Statement 11 does some GC and check the referee of the weak reference ref to judge whether object obj is absorbed and there can be leak source. By the weak reference checking mechanism, the unit test can determine whether the leak risky method may cause leaks.

6 Case studies

To validate the proposed approach, we implemented our approach as an Eclipse plugin and conduct case studies on several memory leak bugs in JDK which are typical examples of the risky modules introduced in section 3.

6.1 MODULES DIRECTLY LEAKING OBJECTS

The modules directly leaking objects are a little hard to find in the JDK memory leak bugs. But many existing bugs can easily be turn into this kind. For example, in Figure 7, we can easily get a representative directly leaking case based on a real memory leak bug JDK-6942989. In the case, there is a loop calling leaking method getAnonymousLogger() (the body of getAnonymousLogger() can be found in Figure 9). The execution rounds of the loop are unbounded and determined by the method's input. In method getAnonymousLogger(), the newly created Logger objects are added into an external container. In other words, the new objects escape from the loop scope. Therefore, the case matches the characteristics of the first kind of leak risky modules.

```
public class Worker {
 public static void doLoggedOperation(int n){
  for(int i = 0; i< n; i++){
       Logger logger = getAnonymousLogger();
       logger.log(record);
       doSth();
  }
}
}
```

FIGURE 7 A case for modules directly leaking objects

```
public class LoggerTest {
@Before
public void setUp() throws Exception {
}
@Test
public void testDoLoggedOperation () throws Exception{
Worker fixture = new Worker();
int n = MemoryTester.LARGE_INT;
long memoryBefore = MemoryTester.getUsedMemory();
fixture. doLoggedOperation(n);
long memoryAfter = MemoryTester.getUsedMemory();
          MemoryTester.assertMemoryGrowth(memoryBefore,
memoryAfter, NO_SIGNIFICANT_GROWTH);
}
}
```

FIGURE 8 Unit test for the case shows in Figure 7

Our approach firstly finds out the loop in method doLoggedOperation. Then, it identifies the loop is input dependent on method parameters. Finally, the approach determines that the newly created objects escape from loop scope. Therefore, the approach identifies the leak risky method doLoggedOperation and then generates the unit test. The unit test is shown in Figure 8. In the unit test, a large input data MemoryTester.LARGE_INT is set for tested method doLoggedOperation to strengthen memory use. When running the unit test, the results show that method doLoggedOperation consumes abnormal amount of memory and hence causes memory leaks. The case indicates our approach is effective in revealing the first kind of leak risky modules.

6.2 MODULES ACCUMULATING NEWLY CREATED OBJECTS

For this kind of leak risky modules, we use memory leak bug JDK-6942989: Memory leak of java.lang.ref.WeakReference objects as the studied case. The bug affects JDK version 4.2u27, 5.0u25, and 6. Its relevant code is briefly shown in Figure 9. In the case, a new WeakReference object created in the method doSetParent (indirectly called by method getAnonymousLogger()) is added into external container kids. Although the weak references are finally broken, there are still references from the external container to the new WeakReference objects. These objects in kids are not released on time. Therefore, the case matches the characteristics of the second kind of leak risky modules, and method getAnonymousLogger() has risk in leaking memory.

```
public class Logger {
   private boolean anonymous;
   private static Object treeLock = new Object();
   private Logger parent;
private ArrayList<LogManager.LoggerWeakRef> kids;
public static Logger getAnonymousLogger() {
  return getAnonymousLogger(null);
}
public static synchronized Logger getAnonymousLogger(String re-
sourceBundleName) {
……;
Logger result = new Logger(null, resourceBundleName);
result.anonymous = true;
Logger root = manager.getLogger("");
result.doSetParent(root);
return result;
}
private void doSetParent(Logger newParent) {
    ……;
    if (parent != null) {
            for (Iterator iter = parent.kids.iterator(); iter.hasNext(); ) {
              WeakReference ref = (WeakReference) iter.next();
Logger kid = (Logger) ref.get();
              if (kid == this) {
                  iter.remove();
                  break;
}
            }
 }
parent = newParent;
……;
parent.kids.add(new WeakReference(this));
   updateEffectiveLevel();
}
}
```

FIGURE 9 Code relevant to bug JDK-6942989

In our approach, we firstly do escape analysis with the escape sources in method getAnonymousLogger() excluding the return value and the parameters by Algorithm 2. Then, we can obtain all the escape objects. Finally, it identifies that the escape objects contain the newly created objects. Therefore, the approach considers method getAnonymousLogger() as risky. The unit test generated by our approach is shown in Figure 10. In the test, we put method getAnonymousLogger() into a loop and set a large upper bound for the loop to strengthen memory use. When running the unit test, the results show that the method getAnonymousLog-ger() can lead to memory leaks and indicate our approach can identify this kind of risky modules.

```
public class LoggerTest {
@Before
public void setUp() throws Exception {
}
@Test
public void testGetAnonymousLogger throws Exception (){
        long memoryBefore = MemoryTester.getUsedMemory();
        for(int i=0;i<MemoryTester.LARGE_LOOPNUM;i++)
Logger.getAnonymousLogger();
        long memoryAfter = MemoryTester.getUsedMemory();
        MemoryTester.assertMemoryGrowth(memoryBefore,
memoryAfter, NO_SIGNIFICANT_GROWTH);
    }
}
```

FIGURE 10 Unit test for case JDK-6942989

6.3 MODULES ABSORBING ARGUMENT OBJECTS

We use memory leak bug JDK-6525563: Memory leak in ObjectOutputStream as the studied case for the third category of risky modules. The bug affects JDK version 6. Its relevant code is briefly shown in Figure 11. In the case, a reference argument obj is passed to method writeObject0. The parameter obj is then added into an external array field objs of the receiver object in method insert which is indirectly called by method writeUnshared. Finally, the argument object will be absorbed inside method writeUnshared. The case matches the characteristics of the third kind of leak risky modules.

```
public class ObjectOutputStream{
private int size;
private int threshold;
private int[] spine;
private int[] next;
private Object[] objs;
public void writeUnshared(Object obj) throws IOException {
writeObject0(obj, true);
}
private void writeObject0(Object obj, boolean unshared) {
int h;
Object orig = obj;
Class cl = obj.getClass();
ObjectStreamClass desc = null;
writeOrdinaryObject(obj, desc, unshared);
}
private void writeOrdinaryObject(Object obj,  ObjectStreamClass
desc,  boolean unshared)
{
        assign(unshared ? null : obj);
}
int assign(Object obj) {
        insert(obj, size);
        return size++;
    }
private void insert(Object obj, int handle) {
        int index = hash(obj) % spine.length;
        objs[handle] = obj;
        next[handle] = spine[index];
        spine[index] = handle;
    }
private int hash(Object obj) {
        return System.identityHashCode(obj) & 0x7FFFFFFF;
    }
}
```

FIGURE 11 Code relevant to bug JDK-6525563

Our approach firstly marks the parameter object passed to method writeUnshared(Object obj) as a special new object by Algorithm 3. Then, we obtain all the escape objects by escape analysis. Finally, it can be found that the escape objects contain the special new object. In another words, the parameter object escapes from the method scope. Therefore, the approach recognizes method writeUnshared(Object obj) as a leak risky module and then gener-ates the final unit test for it (see Figure 12). In the unit test, it uses MemoryTester.prepareArgument(obj) to add a weak reference to the method's reference parameter and use MemoryTester.assertArgumentNotLeaked(ref) to test whether the weak reference have been broken to check memory leaks. While running the unit test, the results show that the test method writeUnshared(Object obj) causes

memory leaks. The case indicates our approach is able to test memory leaks for the third category of risky modules.

```
public class ObjectOutputStreamTest {
@Before
public void setUp() throws Exception {
}
@Test(expected = java.io.NotSerializableException.class)
public void testwriteUnshared() throws Exception{
ObjectOutputStream fixture = new ObjectOutputStream(new ByteAr-
rayOutputStream());
Object obj = new Data();
WeakReference<Object> ref = MemoryTester.prepareArgument(obj);
fixture.writeUnshared(obj);
obj = null;
    MemoryTester.assertArgumentNotLeaked (ref);
}
}
```

FIGURE 12 Unit test for JDK-6525563

The above cases show that the approach can identify and test three kinds of leak risky modules effectively. It can reveal real leaking methods, which could be helpful for practical use.

7 Conclusions

The paper proposes an approach for discovering memory leak phenomenon from testing perspective. The approach automatically generates unit tests to find potential memory leaks in Java methods. It firstly identifies three kinds of leak risky modules. Then, leak-oriented unit tests are generated from normal unit tests to strengthen the ability in finding leaks. We conduct case studies on real bugs. The results show that the approach is effective in revealing real leak modules. The paper focuses on unit testing. In the future, we also plan to do leak testing at system level to further support the discovering of memory leak bugs.

Improved PSO clustering routing algorithm for WSN

Minsheng Tan, Huan Zhou*, Yangwei Li, Jianxue Liu

School of Computer Science and Technology, University of South China, Hengyang Hunan, 421001, China

Received 1 March 2014, www.tsi.lv

Abstract

For cluster head selection randomness of clustering algorithm, and PSOC algorithm were not considered the distance from cluster head to base station, an improved particle swarm optimization (I-PSOC) routing algorithm was brought out. The improved algorithm particle swarm fitness function was improved by considering the node residual energy, nodes' distance and the distance between nodes and base station. At the same time, the optimal nodes were selected as the cluster head and the cluster head has transmitted the data to base station in a single or more jumps through searching right path in the improved algorithm. The simulation results show that the nodes energy consumption of network was reduced significantly and the network life cycle was extended

Keywords: PSO, Clustering Routing Algorithm, cluster head, Wireless Sensor Network

1 Introduction

Wireless Sensor Network (WSN) is relatively large-scale, and has the distribution density of numerous nodes, especially limited energy of sensor node. Therefore, the overall energy consumption of the network must be considered to achieve efficient data transfer, extending the network lifetime. For large-scale WSN, generally being used cluster-based routing algorithm, the network is divided into different clusters, select the cluster head for data integration, and reduce data redundancy [1] is a method for effectively reducing network energy consumption, enhancing network robustness and scalability, and prolonging network lifetime.

The execution of cluster-based routing algorithm is generally divided into four steps: cluster head selection, formation of clusters, intra-cluster and inter-cluster communication. Cluster head nodes not only receive and fuse the date transmitted from other nodes, but also transmit the processed data to the distant station in the same time. So it needs to consume more energy. However, most clustering algorithms used with equal probability select cluster head randomly without taking into account the energy and location information of cluster head, which leads to uneven distribution of cluster head in the network, imbalance in network energy consumption, energy consumption of data communication, premature node death, impact on the entire network life cycle [3].

Particle Swarm Optimization (PSO) is a swarm intelligence optimization algorithm and a community-based collaborative random search algorithm [4, 5], developing by simulating birds foraging behaviour. It has fast search speed, high efficiency, simple algorithm. First, a group of particles is initialized, and then search out the global optimum target area by their own experience and social collaboration. Research shows, PSO find the global optimal solution with relatively high probability and accuracy, so it can be applied to the WSN which has numerous nodes and limited energy for cluster head selection. In this paper, it mainly optimizes the selection of cluster head in clustering routing by improving fitness function, thus, forming the optimal cluster, minimizing sensor node energy consumption, extending the network lifetime [6-8].

2 Analysis of PSO clustering routing algorithm

2.1 PSO INTRODUCTION AND PROCESS

PSO is to solve optimal problems by simulating birds foraging behaviour. Every bird is abstracted as a "particle", and has its own position and velocity to determine the search direction and distance, as well as a value of fitness function to measure particle properties. It initiates a group of particles firstly, and then particles find the global optimal solution in the search space by iteration. Suppose: the community size is M; the *i*-th particle in the search space is defined as $X_i = (x_{i1}, x_{i2}, ..., x_{im})$; the particle velocity is defined as: $V_i = (v_{i1}, v_{i2}, ..., v_{im})$; the optimal location searched by particle i can be expressed as $P_i = (p_{i1}, p_{i2}, ..., p_{im})$; the current optimal location in the group can be expressed as $P_g = (p_{g1}, p_{g2}, ..., p_{gm})$. Each iteration particle updates the information of position and velocity by tracing P_i and P_g. The Equations for updating information of position and velocity are following:

$$V_{id}(t+1) = \omega V_{id}(t) + c_1 r_1 (P_{id} - X_{id}(t)) + c_2 r_2 (P_{gd} - X_{id}(t)) , \quad (1)$$

*Corresponding author's e-mail: tanminsheng65@163.com

$$X_{id}(t+1)=X_{id}(t)+V_{id}(t+1)\ . \quad (2)$$

Parameters and description in the above Equation are shown in Table 1.

TABLE 1 Update the parameters and describe the Equation

V	Velocity of particle
X	location of particle
t	Number of iteration
ω	Weighting coefficient
$c1$,$c2$	Factor of studying
$r1$,$r2$	Random Num in(0,1)
P_{id}	extreme value of Every particle
P_{gd}	extreme value of Every particle
i	The positive integer between [1,M]
d	The positive integer between [1,D]

In Table 1, P_{id} is Individual optimum solution and extreme value of every particle, P_{gd} is all particle group's optimum solution and extreme value of every particle, M is the amount of the particle, D is the biggest dimension in searching zoom.

PSO process is as shown in Figure 1. Its basic steps are following as:

1) Initiate particles, every particle has velocity V_i and position X_i, set the number of iterations as K, and the learning factors as $c1$ and $c2$.

2) According to the fitness function, figure out each particle fitness function value, the compare with P_{id} and P_{gd}, update individual and global optimal solution.

3) Update particle velocity and position by the Equations (1) and (2).

4) Until the end of iterations, repeat the steps (2) and (3).

In large-scale WSN, routing algorithms are used to adopt clustering methods. While PSO mainly optimize the cluster head selection for clustering algorithms and form optimal cluster, and then balance network energy consumption and prolong the network lifetime.

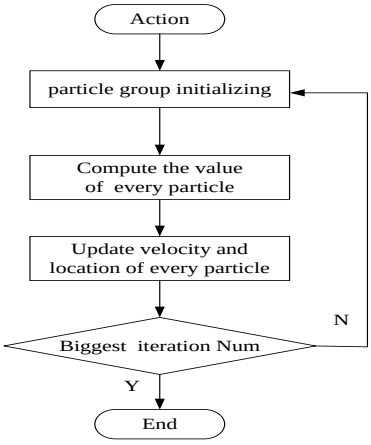

FIGURE 1 Particle swarm algorithm flow chart

2.2 CLUSTERING ALGORITHM

LEACH algorithm is a low-power, self-organizing adaptive clustering routing algorithm. Its execution is cyclical, and it involves two phases in every cycle: establishment of clusters and stable data transmission. LEACH algorithm randomly selected cluster head, so the probabilities of each node becoming a cluster head are equal. This makes the energy consumption of each node is relatively balanced, and then prolong the network lifetime. The two stages process is as follows.

2.2.1 Establishment of clusters

The sensor node generate a random number during [0,1]. Set the threshold as $T(n)$. If node has be selected as cluster head, $T(n)$ is 0, and can't be cluster head any more. While unselected nodes will be elected with equal probabilities $T(n)$. $T(n)$ calculate is as follows:

$$T_{(n)}=\begin{cases}\dfrac{p}{1-p\cdot(r \bmod \frac{1}{p})} & n\in G\\ 0 & Other\end{cases}. \quad (3)$$

In the Equation (3) P is the proportion of cluster head odes number in the network as whole, r is cycles, r *mod* $(1/p)$ is the nodes number. These nodes have been cluster head, G is a set, expressing all unselected nodes in the current cycle.

After selecting cluster head, the cluster head node should inform other non-cluster head node by releasing messages. These nodes select and join to the cluster, which the nearest cluster head belong to, while sending the message to inform its selected cluster head. After all member nodes send messages to inform the cluster head, the cluster head will establish TDMA slot table and broadcast messages to inform all members. Thus, all nodes can send data in each time slot and avoid conflicts when intra-cluster nodes are working.

2.2.2 Stable data transmission

The network will enter a stable data transmission phase after clusters establishment end. Intra-cluster member nodes send the collected monitoring data to the cluster head in its own distributed time slot. Member nodes will be in a sleeping state to save energy during some time that its own time slot is yet to come. While cluster head will always be in working state, sending the data is processed through the fusion to the base station. To avoid signal interference between nearby clusters, different intra-clusters all member nodes can adopt different coding way of CMDA. LEACH algorithm process is described on Figure 2. The algorithm has the following advantages:

1) Randomly select cluster head nodes with equal probability. Relatively balance overall network energy

consumption, save energy, avoid excessive energy consumption of nodes to death and prolong the lifetime of the node.

2) The entire network is divided into multiple clusters, and data communication is involved the intra-clusters and the inter-cluster. So it is more suitable for large-scale WSN.

3) Cluster head fuses the data transmitted from others, and sends them to the base station. Then reduce data redundancy of transmission.

4) Intra-cluster all member nodes has a sleep mode. It will be working condition only when send or receive data.

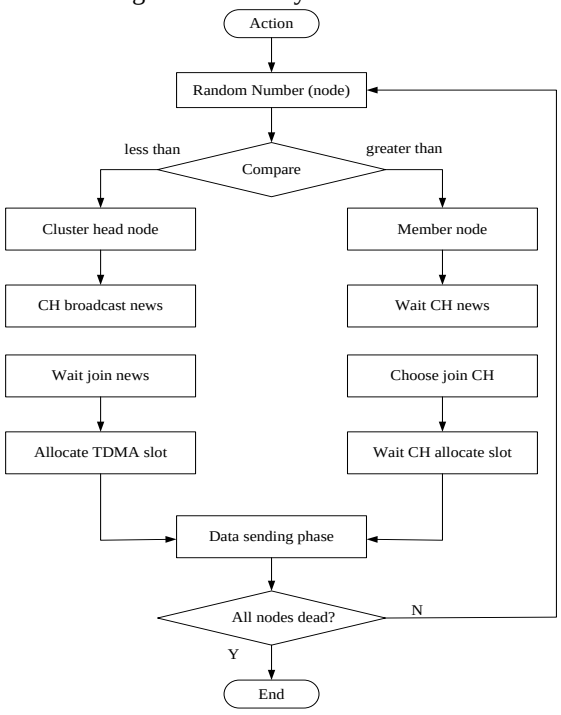

FIGURE 2 Flow chart of the LEACH algorithm

But there are also many disadvantages of LEACH algorithm:

1) Not take into account the position of the cluster head.

2) Not take into account the residual energy of cluster head, cluster head need greater energy consumption for conducting data fusion.

3) Communication between cluster head and sink node use single-hop routing. When aggregation node farther away from the cluster head in the cluster, because of excessive power consumption will prematurely die, and then affect network connectivity.

4) After the network operates stably for a period of time, a new cycle cluster head selection should be conducted again.

2.3 DESIGN REQUIREMENTS OF PSO CLUSTERING ROUTING ALGORITHM

In the design of particle swarm clustering algorithm, we must take into account the following aspects:

1) With an appropriate fitness function, the fitness function setting has an important impact on the algorithm.

2) With the appropriate updating algorithm, to update the particle velocity and position information.

3) With adjustable optimization parameters, make the results do not deviate from the correct solution.

Many scholars at home and abroad research PSO algorithm to implement network optimization clustering problem. In spite of the particle swarm optimization algorithm has many advantages, but there are also easy to fall into local optimum. We mainly improve the parameters of the fitness function in algorithm, the topology structure, the inertia weight, learning factors and mixed strategy, such as paper 47 28 49 and 50, of which more representative is 50 PSOC algorithm, effectively balance the network energy consumption, although it considers the nodes energy and the distance between nodes within cluster, but it without considering the effect of cluster heads and base station distance. If the distance is larger, cluster heads are very easy to premature deaths due to energy consumption too fast.

This article, mainly, improve the situation aimed at selecting cluster heads random in clustering algorithm and PSOC algorithm problems.

3 Improvement of particle swarm cluster routing algorithm

3.1 ALGORITHM IMPROVEMENT SCHEME

Firstly, network has been divided into different clusters by using clustering algorithm, set a threshold energy, and then form a candidate cluster heads set, then combined with improved fitness function, according to the candidate set of cluster heads within each node's residual energy and location, using PSO algorithm, select the global optimal node as the cluster head, cluster heads broadcast information, transmit and receive within the cluster node's residual energy and location information, and to establish a time slot table, for each of the distribution of cluster nodes when the TDMA slots. The main function of Cluster member nodes is testing the object of data collection, and transmitting data to the cluster head, cluster heads not only collect the data, but also transmit the data fusion in the cluster member nodes, finally, through single hop or multiple hops they send the date to the base station (gathering node).

The method can efficiently prolong the network life cycle, the network node have the opportunity to become a cluster head when the network node energy is higher than the energy threshold set. if the cluster head suddenly die or energy is lower than the threshold, the network node will be back for cluster heads selection, The shortage for clustering algorithms when it used data transmission in one hop paths which lead to far from the base station of the premature death of cluster nodes, in the data communication stage, the cluster heads sent to the distances from the base station or base station of cluster nodes in the cluster based on decision fusion data. Cluster heads choose the appropriate path to base station. This

method can effectively reduce the network energy consumption and prolong the network life cycle.

3.2 NETWORK MODEL

Network model of this paper is shown in Figure 3, and the research of wireless sensor network makes the assumption.

1) Node and base station position is fixed, base station far away from node distance, cluster heads selection is not affected by the environment.

2) The nodes know their position information and residual energy.in addition to the base station, the rest of the initial energy of nodes and processing power are equal, the same communication range.

3) The node transmission power can be adjusted according to the communication distance.

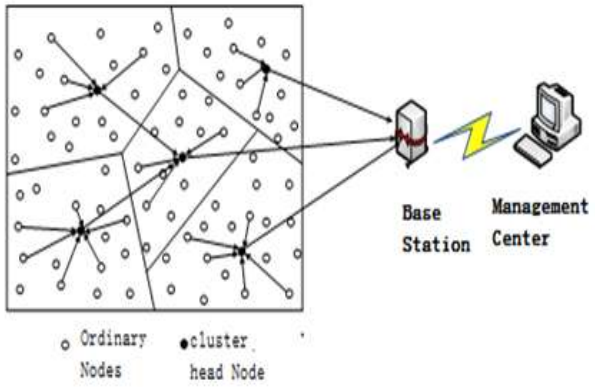

FIGURE 3 The structure of the network

3.3 ENERGY MODEL

In this paper we use the first-order energy consumption of wireless communication model, as shown in Figure 4. The model is based on the following assumptions:

1) The node energy limited.

2) The node energy consumption is basically the same.

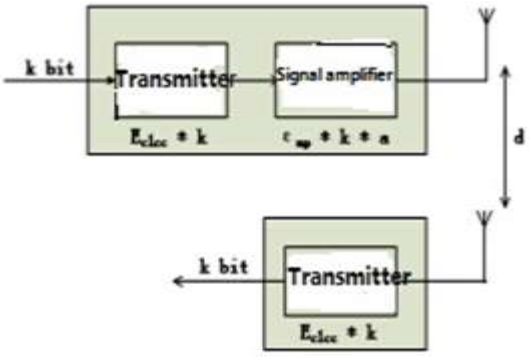

FIGURE 4 Wireless communication energy model

Form of the energy consumption according to the attenuation of power amplifier can be divided into two parts: free space model and the multipath attenuation model. Attenuation model, power amplifier based on node spacing selection for d0 set threshold method, the distance between nodes is d, if d < d0, multipath attenuation model is adopted, therefore, when Kbit node transmission data information, the energy consumption between sensor nodes can be represented as:

$$E_{Tx}(k,d)=\begin{cases} E_{elec}\cdot k+\varepsilon_{fs}\cdot k\cdot d^2 (d<d_0) \\ E_{elec}\cdot k+\varepsilon_{mp}\cdot k\cdot d^4 (d\geq d_0) \end{cases}. \tag{4}$$

$$E_{Rx}(k)=E_{elec}\cdot k \tag{5}$$

Among the equation above, the $E_{Tx}(k,d)$ represents the energy consumed by the transmission of k bits data, the $E_{Rx}(k)$ represents the energy consumed by the reception of k bits data, the E_{elec} represents the energy consumed by the transmission of 1 bit data, respectively, ε_{fs} and ε_{mp} represent the power amplifier circuit to model consumption coefficient of multi-path model and the free space attenuation, d is the distance that data transmitted, d_0 is the threshold distance set.

3.4 IMPROVEMENT OF FITNESS FUNCTION

Evaluate the quality of the selected cluster head based on the fitness function, we mainly consider the three aspects of content. Firstly is the cluster head energy evaluation factor f_1. Cluster energy takes the inverse proportion of the total energy S_f the nodes within the cluster. Cluster heads should not only accept the quantity of node data but also transmitted the data to base station. The largest energy consumption, therefore, cluster heads residual energy is larger, the better. Secondly, evaluation factor f_2, stand for the average distance of the node to the cluster head, the smaller the average distance, the less data transmission energy consumption between nodes. Thirdly, evaluation factor f_3, stand for cluster heads to the base station distance, the smaller the best path to the base station, the smaller consume energy cluster head used, hypothesis, network consists of M nodes, divided into k clusters, the improvement of fitness function is as follows:

$$\mathrm{f}=\alpha f_1+\beta f_2+\gamma f_3, \tag{6}$$

$$f_1=\sum_{j\in(C_i)} E(n_j) \Big/ E(CH_i), \tag{7}$$

$$f_2=\sum_{j\in(C_i)} \mathrm{d}(n_j,CH_i) \Big/ |C_i|, \tag{8}$$

$$f_3=\min_{k=1,2,\ldots,K}\{\mathrm{d}(CH_i,BS)\}. \tag{9}$$

According to (6), it calculates particle fitness function value, select the global optimal node as the cluster head. Fitness function value is smaller, the residual energy of the

cluster heads is much more or the distance between the cluster member nodes and cluster heads is closer, the distance between cluster and the base station is closer.

3.5 DETAILED STEPS OF ALGORITHM IMPROVEMENT

Network nodes could be divided into different clusters, this paper uses PSO algorithm to select the global optimal node as the cluster head, and find the optimal cluster. The cluster heads through single hop or multiple hops, and then transmit data after fusion methods to the base station and balance network energy consumption and prolong the network life cycle. I-PSOC algorithm in this paper and the cluster head selection cycles, each cycle is divided into clusters of establish and stability of the data transmission phase. Include the cluster initialization of the candidate, according to the improvement of the fitness function to select the optimal cluster heads and the formation of optimal cluster; Data transmission phase including the cluster-heads data transmission and data transmission between clusters. Its algorithm steps are as follows:

Step 1. Initialize clustering of network, set up energy threshold E_T, when the node energy is greater than E_T, it have a chance to become cluster head. Assume the $CH_{candidate}$ represents the set of candidate cluster:

$$CH_{candidate} = \{n_i \mid E_i > E_T\},$$

and the $E_T = \sum_{i=1}^{M} E_i / M$.

E_i represents the remaining energy of current node, M represents the total number of nodes in the network. Although, determined the candidate cluster head basically at this stage, only consider the residual energy, ignoring the wasted energy that cluster head caused for the uneven distribution, therefore need to improve the fitness function, select the optimal cluster head from the candidate cluster head collection.

Step 2. Improve the fitness function, select the optimal cluster head. Initialize candidate of cluster particles, calculate the particle's fitness, adopt iterative method to update particle's speed and position, until the cessation of reaches maximum number of iterations of the algorithm, the global optimal solution will become the cluster head.

Basic steps are as follows:

Step 1. Initialize the particle swarm. initial speed and position of particles in the candidate set of cluster heads, calculate each particle's fitness by the Equation (6), and initialize the particle position as the individual optimal solution P, choose to adapt the value of the smallest particles as the global optimal solution of the whole particle P1.

Step 2. Update the particle's position and speed. According to the Equations (1) and (2) get each particle's new position and speed, and calculate a new adaptive value f_1 by the Equation (6).

Step 3. Update the individual optimal solution. Compare the i-th particle current fitness fi and individual optimal solution P. If f_i < P, it updates the P, on the other hand, keep P.

Step 4. Update the global optimal solution. Compare the smallest individual optimal solution in the particle swarm and the initial global optimal solution of the whole particle swarm P1. If less than P1, the individual optimal solution of particles become the global optimal solution of the whole particle P1, otherwise, keep P1.

Step 5. Repeat steps (2), (3) and (4), until the maximum number of iterations, and then end of the recycle. Select the global optimal solution as the cluster head.

Algorithm process is shown in Figure 5.

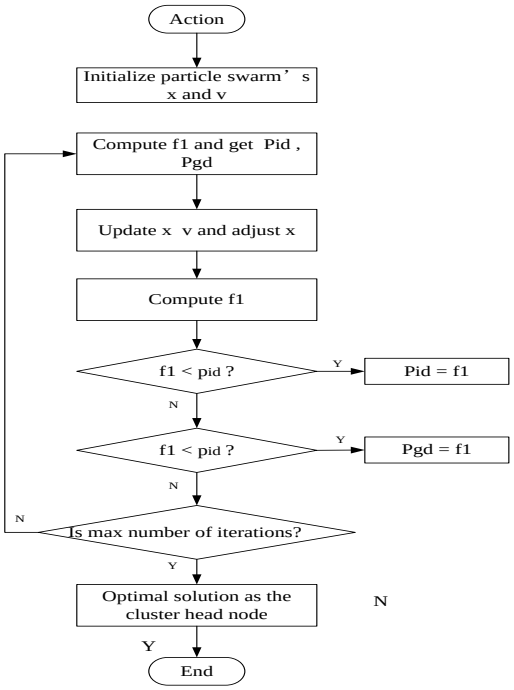

FIGURE 5 Improved cluster heads selection algorithm

3.6 THE FORMATION OF OPTIMAL CLUSTER

After using the I-PSOC algorithm to select cluster head, each node choose to join the cluster according to the sent message signal strength when it receives, and sent its energy and location information to cluster heads. The cluster head nodes allocated time slot for each members. Stable data transmission phase:

1) Data transmission phase in the clusters. After form optimal clusters, cluster member nodes will collect data transmission to the cluster head in its own slot, the rest of the time it dormant to save energy.

2) Data transmission between clusters. The stage mainly is cluster head accept the members of cluster nodes transmit data and fusion, and then choose the appropriate path to transmit data according to the distance of cluster heads to the base station.

Limited distance value d0, and generally take the average distance of the cluster heads to the base station. If the distance from the base station to cluster head d>d0, then the cluster head search the optimal path for transmitting the merged data to the base station by the multi-hop way. Else d<d0, cluster head will be directly to transmit the merged data to the base station by the single-hop way.

When the node and the base station are fixed, this cluster head selection process is not affected by environmental factors. If the cluster head energy is below the energy threshold E_T, then re-select for cluster head. The selected node as the cluster head global optimal way, balancing the network energy consumption, thus effectively extending the network life cycle.

4 Simulation and result analysis

4.1 THE PERFORMANCE OF I-PSOC ALGORITHM EVALUATION INDEX

In this paper the improved routing algorithm evaluation mainly consider the following aspects: network life cycle, the network energy consumption.

1) Network life cycle can be expressed as the relationship between the number of nodes in the network and the survival time (number of rounds) of running.

2) Energy consumption of the network can be expressed as the energy of all nodes in the network over time, of the remaining amount of energy consumed.

4.2 SIMULATION ENVIRONMENT AND PARAMETER SETTINGS

To verify the improved performance of the algorithm, use TOSSIM tools for simulation, to carry out large-scale network simulation, to imitate the behaviour of the hardware resources, through to the hardware simulation component changes, can provide a variety of different hardware environment performance, meet the requirements of different users.

TABLE 2 Energy simulation parameters

Parameter	Value
E_{abc}	50nJ/bit
E_{DA}	50nJ/bit/singal
$\varepsilon_{\varepsilon}$	10pJ/bit/m^2
ε_{mp}	0.0013Pj/bit/m^4
E_0	0.5J
Package's length	4000bits

In this article, through TOSSIM simulation tools from two aspects of the network life cycle and the network energy consumption compared with LEACH and PSOC algorithm Using Figure 4 wireless communication model and energy consumption is calculated using the Equation (4). Simulation environment: the 100 sensor nodes randomly distributed within the 100x100m square area, the base station is located in (= 50 X, Y=150). The simulation parameters are shown in Table 2. The parameters of the particle swarm optimization algorithm for: α=0.35, β=0.35, γ=0.3, ω=0.9, learning factor c1=2, c2=2.

4.3 EXPERIMENT AND RESULT ANALYSIS NETWORK LIFE CYCLE COMPARED

The I-PSOC algorithm simulation, record and with LEACH algorithm and PSOC compare the amount of surviving nodes. Suppose among the node does not appear data retransmission and the phenomenon of transmission errors, and the members of the cluster nodes without transferring data in a sleep states. Simulation in this paper, a total of 750 rounds, discrete simulation get round number and node number offered as shown in Tables 3 and 4.

TABLE 3 The relations between total number of rounds and surviving nodes

Rounds surviving nodes	0	100	200	300	400
LEACH	100	100	100	95	80
PSOC	100	100	100	100	90
I-PSOC	100	100	100	93	85

TABLE 4 The relations between total number of rounds and remaining energy

Rounds surviving nodes	500	600	650	700	750
LEACH	52	20	0	0	0
PSOC	68	40	20	0	0
I-PSOC	75	49	33	16	0

Surviving nodes in the network and simulation rounds relationship shown in Figure 6. The simulation results show that compared with LEACH and PSOC algorithm, with the number of rounds progressed, the I-PSOC algorithm in the number of surviving nodes significantly more. PSOC algorithm is not survive more node than the I-PSOC algorithm, but still want to survive more than LEACH algorithm nodes, if all node dies, the I-PSOC algorithm in the network experienced a number of rounds is clearly more than LEACH and PSOC algorithm, It can be seen, the paper improved PSOC fitness function selected as the cluster head global optimal solution, compared to LEACH algorithm randomly selected cluster head and PSOC algorithm does not consider the distance between cluster head and the base station method, network significantly less energy consumption, extended lifetime effectively.

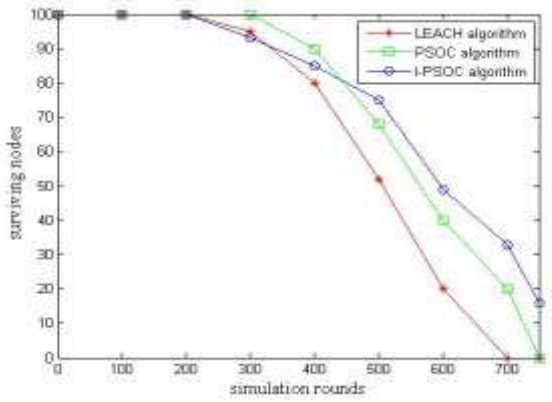

FIGURE 6 Network life time contrast

4.4 NETWORK ENERGY CONSUMPTION COMPARED

On improved particle swarm routing algorithm simulation, record the total residual energy of network nodes, and with LEACH and PSOC algorithm total residual energy of network nodes for comparison. This co-simulation 750, discrete number of rounds simulated node residual energy relationship shown in Tables 5 and 6.

TABLE 5The relations between total number of rounds and remaining nodes

Rounds remaining energy	0	100	200	300	400
LEACH	50	47	42	35	27
PSOC	50	48	44	38	32
I-PSOC	50	48	45	40	34.5

TABLE 6 The relations between total number of rounds and remaining energy

Rounds remaining	500	600	650	700	750
LEACH	17	6	0	0	0
PSOC	25	15	8	0	0
I-PSOC	28	19	14	7	0

Network nodes remaining energy relations with simulation round number is shown in Figure 7. The simulation results show that when going through the same number of rounds, the I-PSOC algorithm in network nodes significantly more total residual energy, PSOC algorithm followed, LEACH algorithm in network energy consumption the most. Therefore, the I-PSOC algorithm can effectively prolong the network lifetime. That is the cluster head selection algorithm in the first set when an energy threshold, the candidate cluster head constitute a collection through I-PSOC fitness function, selection from the candidate set of cluster heads the global optimal solution as the cluster head, forming optimal clusters. While inter-cluster communication, also set a distance d0, if the distance between the cluster head and the base station is smaller than d0, transmit data in a single jump directly, else, the cluster head will search for the most suitable path to transmit the merge data to the base station by multi-hop way, effectively balancing the network energy consumption and prolong the life cycle.

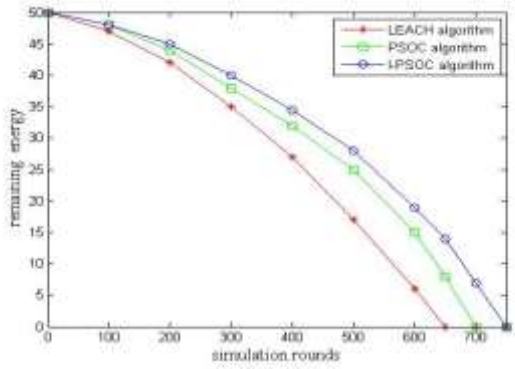

FIGURE 7 The remaining energy of nodes in the network contrast

5 Conclusions

This paper first introduces the basic principles of particle swarm algorithm and algorithm-step process, and made a careful analysis of particle swarm clustering routing algorithm. Then according to the clustering algorithm of cluster head selection of randomness and PSOC algorithm does not take into account the distance cluster head and base station, etc. From the node residual energy distance between nodes and the node and the base station distance to consider, improved particle swarm fitness function, select the globally optimal node as the cluster head, forming optimal cluster. Meanwhile, the intra-cluster communication using single-hop transmission of data, the inter-cluster communication from the base station in accordance with the distance of cluster heads choose the right path (single-hop or multi-hop) to transfer data to a base station. Finally introduces TOSSIM discrete simulation tools, build a simulation environment, set energy consumption parameters and use TOSSIM simulation tools. From two aspects of the network life cycle and energy consumption to evaluate the performance of the I-PSOC algorithm, compared with LEACH and PSOC algorithm simulation results, analysis shows that the I-PSOC algorithm significantly reduces the network energy consumption, effectively prolong the network life cycle.

Theoretical analyses and numerical simulation of the interaction time and the separation time of two elastic bars after the loading of a triangular wave

Wei Zhong*, Ming Lei, Zhou Tian

Northwest Institute of Nuclear Technology, Xi'an 710024, Shaanxi Province, China

Received 1 October 2014, www.cmnt.lv

Abstract

With theoretical analyses, the stress-wave propagation and reflection between two elastic bars, whose left side achieved a triangular wave load, is mainly studied. Considering the effects of pulse width of the load, length and wave impedance of the bars and the relationship between the length of the load wave and the two bars, the regularities of the stress-wave propagation and reflection between the two bars is analysed, and the formulas for calculating the interaction time and the separation time of the two bars are derived, in three different conditions. The same problems in three different conditions are simulated by using AUTODYN, and curves of displacements of points at contact surface of the two bars varying the time are given. According these curves, the simulating results of the separation time can be obtained. By the comparison of the simulating results and the theoretical calculated results using formulas derived in this paper, the correctness of the theoretical analyses and formulas here is demonstrated.

Keywords: triangular wave load, elastic bar, separation time, theoretical analyses, AUTODYN

1 Introduction

With the rapid development of high-tech, the field of such relate to explosion and shock problem as national defence technology, aerospace industry, new material technology, etc, is more and more widely, especially in areas such as the arms penetration and explosion, high-speed impact, dynamic response materials, structural damage and other protective aspects [1]. As we know, the study of those problem mentioned above is related to the stress wave propagation. Stress wave propagation characteristics in multi-layer composite structure are a newly rising research field [2-4]. Although the current experimental study of homogeneous material for macroscopic dynamic mechanical behaviour and impulse response has developed many ripe methods, such as Taylor test, split Hopkinson pressure bar, flat impact and detonation technology [5-7], the structures of the actual project are usually layer structures stacked by a variety of materials with different physical properties. Because of light quality, strong design, good performance and strong impact absorbing characteristics of these kind of structures, they have become one of the hot issues of structural engineering applications in recent years [8]. Taking into account that the multi-layer dielectric stress wave propagation problem in the actual project is very complicated, as a theoretical analysis here, the research was focused on the stress wave propagation and reflection of two elastic bars after the loading of a triangular wave. Recently, the most widely application of experimental studies of such problem is the split Hopkinson pressure bar's (SHPB) [9, 10], also known as the Kolsky bar. SHPB technology is on the basis of one-dimensional stress wave theory, which requires the long-thin-bar is linear, isotropic and the dispersion effect can be ignored, meanwhile, the cross-section of the bar in the axial direction is assumed to be a constant and the bar to maintain flexibility and uniform stress state in the process of loading and unloading [11]. As a theoretical analysis of the situation above, the theoretical analysis of this article and the following derivation is also based on the same requirements above.

2 Theoretical analysis and calculation formula derivation

In Figure 1, two elastic bars contact with each other, and a input triangular wave loads with the wavelength of λ acts on the left of bar 1. In the following, the interaction time and the separation time of the two bars will be analyzed. L_1 and L_2 is respectively the length of bar 1 and bar 2, as well as c_1 and c_2 the triangular-wave propagation velocity in bar 1 and bar 2. We assume that the two bars are the same, that is to say, c_1 and c_2 are equal, and can be taken as c. Next, we will prove that the interaction time and the separation time of the two bars are determined by λ, L_2, c_2, and the relative relationship between λ and L_2.

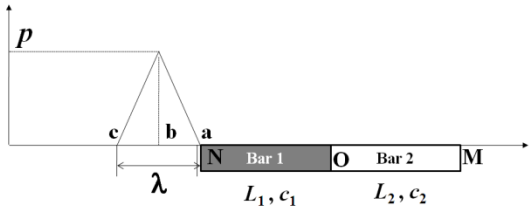

FIGURE 1 Model sketch of this problem.

2.1 CASE 1: $\lambda/2<L_2$

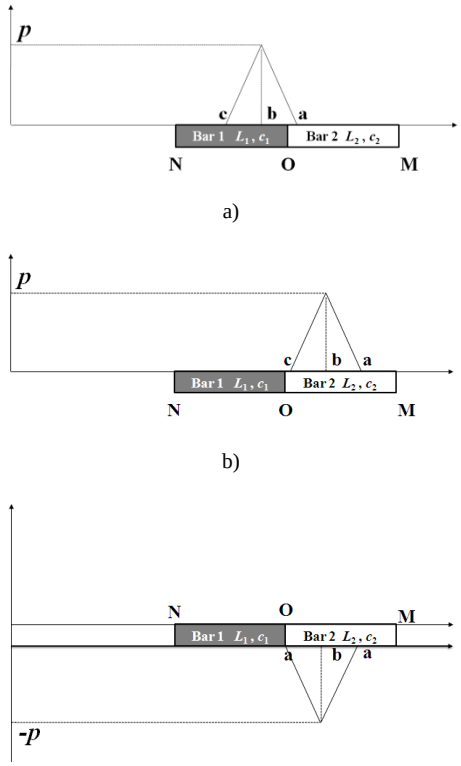

FIGURE 2 Diagram of the stress-wave propagation when $\lambda/2 < L_2$

Since the load is linear and the bars are elastic, the relationship between stress in bars and the input load is linear. Therefore, for easy discussion, the stress of bars will be expressed in the input load in following analysis.

When the front of the stress wave come location O, which is the contact surface of bar 1 and bar 2, the interaction force between the two bars occurs, and compressive stress appears in these two bars, as shown in Figure 2a. When the end of the stress wave passes location O, the interaction force disappears, and the two bars have a same velocity, as shown in Figure 2b. Then, the interaction time of bar 1 and bar 2 can be obtained by:

$$t_{\text{interaction}} = \frac{\lambda}{c}. \tag{1}$$

When the stress wave comes to location M, which is the right end of bar 2, stress wave reflection occurs at the free surface, and an extension wave propagation to the left appears [12]. Particles of the bar will get a velocity to the right after the pass of the extension wave. So when the extension wave comes to the location O, bar 1 and bar 2 will separate from each other, as shown in Figure 2(c). Then, the separation time of bar 1 and bar 2 can be obtained by:

$$t_{\text{separation}} = \frac{L_1 + 2L_2}{c}. \tag{2}$$

2.2 CASE 2: $\lambda/2 > L_2$ and $\lambda/2 < (L_1+L_2)$

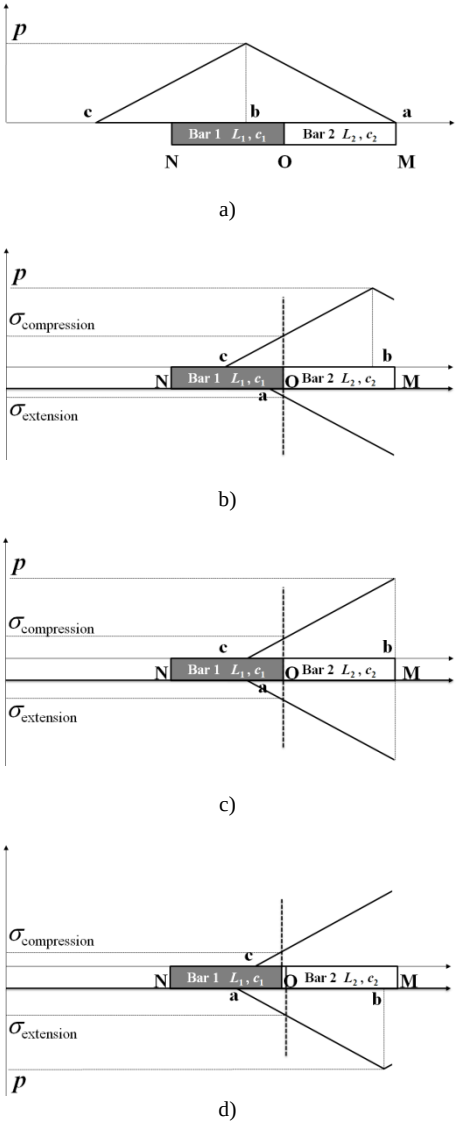

FIGURE 3 Diagram of the stress-wave propagation when $\lambda/2 > L2$ and $\lambda/2 < (L1+L2)$

When the front of the stress wave come location O, the interaction force between the two bars occurs, and compressive stress appears in these two bars, as shown in Figure 3a. When the front of the stress wave comes to the right end of bar 2 but the mid of the stress wave has not come to location O, stress wave reflection occurs at the

free surface, and an extension wave propagation to the left is formed. At the time of this extension wave comes to the location O, the end of the stress wave has not come to the location O yet, and meanwhile, the compressive stress is higher than the stress generated by the reflection extension wave, so the interaction force between bar 1 and bar 2 is always maintained, which will keep the two bars contacting with each other and moving together, as shown in Figure 3b. As the mid of the stress wave comes to the right end of bar 2 and the front of the tensile stress wave passes the location O, although the end of the stress wave has not come to the location O, the tensile stress at location O is equal to the input stress, which means the stress at location O is zero at this time, which can be seen in Figure 3c. As shown in Figure 3d, with the continuing wave propagation, bar 1 and bar 2 will separate from each other, and the separation time of bar 1 and bar 2 can be obtained by:

$$t_{\text{separation}} = \frac{0.5\lambda + L_1 + L_2}{c}. \tag{3}$$

According to the analysis above, it is easy to get the interaction time of bar 1 and bar 2 by:

$$t_{\text{interaction}} = \frac{0.5\lambda + L_2}{c}. \tag{4}$$

2.3 CASE 3: $\lambda/2 > (L_1+L_2)$

This is a very complex case, and the interaction time and separation time are closely related to the waveform of the input stress. In order to make the research more convenient, a special stress wave propagation graph was made, which was shown in Figure 4.

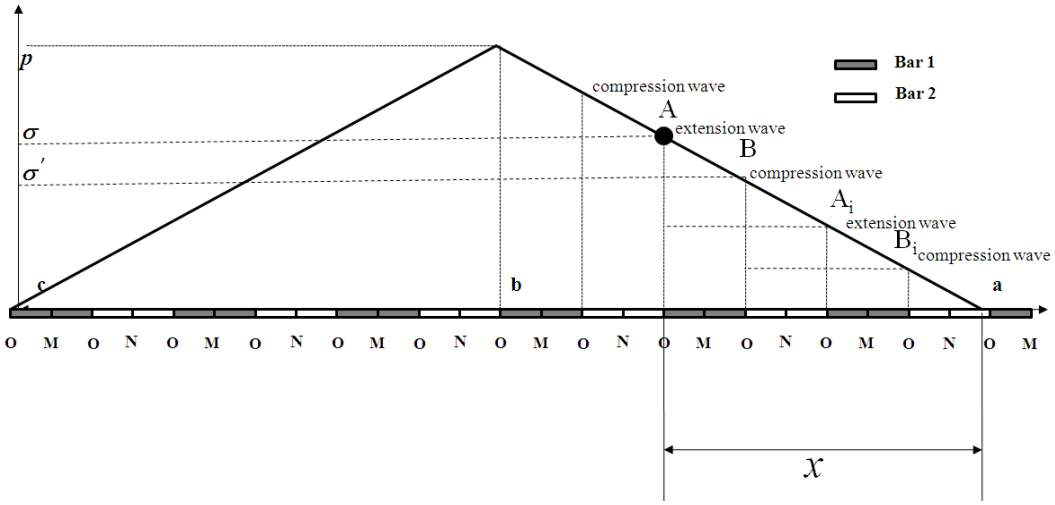

FIGURE 4 Diagram of the stress-wave propagation when $\lambda/2 > (L_1+L_2)$

Assume the distance between the front wave and the extension wave A is x at the time of the extension wave A comes to location O the first time. The relationship between the tensile stress and the compression stress were given in Figure 4. For example, the stress in location B appears, when the extension wave comes to the M free surface - that is, after the input stress wave reflected in the left free surface of bar 1, a reflect compression wave formed, with the wave propagation continuing a length of bar 1, the compressive stress in contact surface of bar 1 and bar 2 appears. Other cases have the similar analysis above.

It is easy to be proved that there is a range of x, and the range is not larger than half of the wavelength. If x is equal to half of the wavelength, the location A will be the top of the input wave when the reflection extension wave comes to location A at the first time. And this location A is where the tensile stress of the contact surface could rise to a maximum. The Equation of the tensile stress and the compressive stress will be derived next.

2.3.1 Tensile stress

The slope of the triangular wave is:

$$k = \frac{p}{\lambda / 2}. \tag{5}$$

From geometrical relations in Figure 4, the slope on the expression of stress and x is:

$$k = \frac{\sigma}{x}.$$

Then:

$$\sigma = k \cdot x. \tag{6}$$

According to Figure 4, it is easy to know the number of the tensile stress waves reflected back and forth at this point is:

$$N = \left[\frac{x}{2(L_1 + L_2)}\right] + 1 \quad 3 \tag{7}$$

The symbol【 】indicates that the number is rounded to the nearest whole number.

For the *i*-th reflection (*i*≥2), the tensile stress satisfies the following Equation:

$$k=\frac{\sigma-\sigma_i}{(i-1)\times[2(L_1+L_2)]}.$$

Then:

$$\sigma_i=\sigma-k\times(i-1)\times[2(L_1+L_2)]. \tag{8}$$

All the tensile stress at the contact surface is the sum of σ_i:

$$\sigma_{\text{tensile}}=\sigma+\sum_{i=2}^{N}\{\sigma-k\times(i-1)\times[2(L_1+L_2)]\}. \tag{9}$$

2.3.2 Compressive stress

The compressive stress at location B can be obtained from geometrical relations in Figure 4:

$$\frac{\sigma\text{-}\sigma'}{2L_1}=k.$$

Then:

$$\sigma'=\sigma-k\times 2L_1 \tag{10}$$

As the same, according to Figure 4, it is easy to know the number of the tensile stress waves reflected back and forth at this point is:

$$M=【\frac{x-2L_1}{2(L_1+L_2)}】+1. \tag{11}$$

For the *i*-th reflection (*i*≥2), the compressive stress satisfies the following equation:

$$k=\frac{\sigma'-\sigma'_i}{(i-1)\times[2(L_1+L_2)]}.$$

Then:

$$\sigma'_i=\sigma'-k\times(i-1)\times[2(L_1+L_2)] \tag{12}$$

So, all the tensile stress at the contact surface is the sum of σ'_i:

$$\sigma_{\text{compressive\_reflect}}=\sigma'+\sum_{i=2}^{M}\{\sigma'-k\times(i-1)\times[2(L_1+L_2)]\} \tag{13}$$

When $(\frac{\lambda}{2}-x)\geq 2L_2$, we get:

$$\frac{\sigma_{\text{compressive\_incident}}-\sigma}{2L_2}=k.$$

Then:

$$\sigma_{\text{compressive\_incident}}=\sigma+k\times 2L_2. \tag{14-1}$$

When $0<(\frac{\lambda}{2}-x)<2L_2$, we get:

$$\begin{cases}\dfrac{p-\sigma}{\delta}=k\\ \dfrac{p-\sigma_{\text{compressive\_incident}}}{2L_2-\delta}=k\end{cases}.$$

Where δ is the distance between location A and the mid of the wave, so:

$$\sigma_{\text{compressive\_incident}}=2p-2L_2k-\delta \tag{14-2}$$

From (13), (14-1) and (14-2), we obtained the total compressive stress:

$$\begin{aligned}\sigma_{\text{compressive}}&=\sigma_{\text{compressive\_reflection}}+\sigma_{\text{compressive\_incident}}\\&=\sigma'+\sum_{i=2}^{M}\{\sigma'-k\times(i-1)\times[2(L_1+L_2)]\}\end{aligned} \tag{15}$$

$$\begin{cases}+\sigma+k\times 2L_2 & (\frac{\lambda}{2}-x)\geq 2L_2\\ +2p-2L_2k-\sigma & 0<(\frac{\lambda}{2}-x)<2L_2\end{cases}$$

If tensile stress is larger than compressive stress on the contact surface, bar 2 and bar 1 will separate from each other.

Assume $\sigma_{\text{tensile}}=\sigma_{\text{compressive}}$, we get $x_{\text{separation}}$:

$$x_{\text{separation}}=\begin{cases}\dfrac{1}{[N-(M+1)]}\times\{2L_2-2L_1M+\\ \sum_{i=M+1}^{N}[k(i-1)\times 2(L_1+L_2)]\} & (\frac{\lambda}{2}-x)\geq 2L_2\\ \dfrac{1}{[N-(M-1)]}\times\{2p/k-2L_2\\ -2L_1M+\sum_{i=M+1}^{N}[k(i-1)\times 2(L_1+L_2)]\} & 0<(\frac{\lambda}{2}-x)<2L_2\end{cases} \tag{16}$$

and:

$$\begin{cases}k=\dfrac{p}{\lambda/2}\\ N=【\dfrac{x}{2(L_1+L_2)}】+1.\\ M=【\dfrac{x-2L_1}{2(L_1+L_2)}】+1\end{cases} \tag{17}$$

So the separation time of bar 2 and bar 1 can be got by:

$$t_{\text{separation}}=\frac{x_{\text{separation}}+L_1+2L_2}{c}. \tag{18}$$

And the interaction time:

$$t_{\text{interaction}} = \frac{x_{\text{separation}} + 2L_2}{c}. \quad (19)$$

Equations (16) and (18) shows that, the separation time and the interaction time of bar 1 and bar 2 are determined by the length of bar 1 and bar 2, the length of the stress wave and the wave resistance (equals to the product of stress wave propagation velocity and the density of the bars).

If the calculation results of Equation (16) is that $x_{\text{separation}}$ is larger than length of the wave, bar 1 and bar 2 will not separate, although the reflective tensile stress of the end of the input wave has arrived at the contact surface of the two bars. Then, for this situation, the two bars will always move together, and never separate from each other. This situation is actually a completely inelastic collision.

3 Numerical simulation and verification

In order to verify the correctness of the theoretical analysis above, numerical simulation of the three cases above has been carried out by AUTODYN, and results of the separation time were given. The comparison between these numerical results and the analytical solutions according to the theoretical analysis in this paper has been done also.

In the following simulation and computation, bar 1 and bar 2 are both the 20 # steel (E=210 GPa, ρ=7.82 g/cm^3, μ=0.28), as well as the length both 1 metre.

3.1 CASE 1: $\lambda/2 < L_2$

Conditions of the input triangle wave: σ_0=300 Mpa, λ=292.96 mm.

The numerical simulation has been done by AUTODYN, and the results of displacement of points at the right side of bar 1 and the left side of bar 2 varying the time was shown in Figure 5.

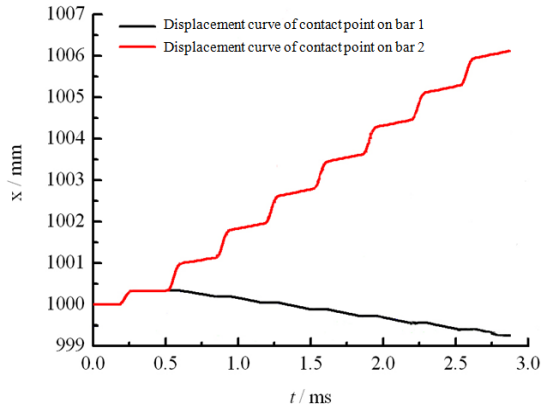

FIGURE 5 Curves of displacement of points at the right side of Bar 1 and the left side of Bar 2 varying the time

According to the simulations and Figure 5, we got the separation time of bar 1 and bar 2 was about 0.5117 ms.

As the elastic wave velocity in the bars is:

$$c = \sqrt{\frac{E(1-\mu)}{(1+\mu)(1-2\mu)\rho}} = 5859.24 \quad \text{mm/ms}.$$

According to Equation (2), we got:

$$t_{\text{separation}} = \frac{L_1 + 2L_2}{c} = 0.5120 \quad \text{ms}.$$

The relative error was:

$$\eta = \frac{0.5120 - 0.5117}{0.5117} = 0.058\%.$$

And the interaction time of bar 1 and bar 2 could also been obtained from Equation (1):

$$t_{\text{interaction}} = \frac{\lambda}{c} = 0.1 \quad \text{ms}.$$

3.2 CASE 2: $\lambda/2 > L_2$ and $\lambda/2 < (L_1+L_2)$.

Conditions of the input triangle wave: σ_0=300 Mpa, λ=1464.80 mm.

The numerical simulation has been done by AUTODYN, and the results of displacement of points at the right side of bar 1 and the left side of bar 2 varying the time was shown in Figure 6.

According to the simulations and Figure 6, we got the separation time of bar 1 and bar 2 was about 0.63 ms.

As the elastic wave velocity in the bars is:

$$c = \sqrt{\frac{E(1-\mu)}{(1+\mu)(1-2\mu)\rho}} = 5859.24 \quad \text{mm/ms}.$$

According to Equation (2), we got:

$$t_{\text{separation}} = \frac{0.5\lambda + L_1 + L_2}{c} = 0.5913 \quad \text{ms}.$$

The relative error was:

$$\eta = \frac{0.63 - 0.5913}{0.63} = 6.1\%.$$

The interaction time of bar 1 and bar 2 could also been obtained from Equation (1):

$$t_{\text{interaction}} = \frac{0.5\lambda + L_2}{c} = 0.4206 \quad \text{ms}.$$

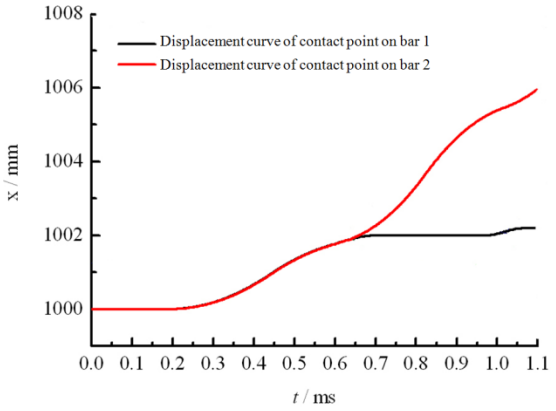

FIGURE 6 Curves of displacement of points at the right side of Bar 1 and the left side of Bar 2 varying the time

3.3 CASE 3: $\lambda/2 > (L_1+L_2)$

Conditions of the input triangle wave: σ_0=300 Mpa, λ=14648 mm.

The numerical simulation has been done by AUTODYN, and the results of displacement and velocity of points at the right side of bar 1 and the left side of bar 2 varying the time was shown in Figure 7 and Figure 8.

With reference to Figure 7 and Figure 8 we could see that bar 1 and bar 2 almost always move together, and don't separate from each other. Figure 8 showed that, during the first 5 ms, velocities of bar 1 and bar 2 have been increasing. After the first 5 ms, both bars travelled in a constant velocity.

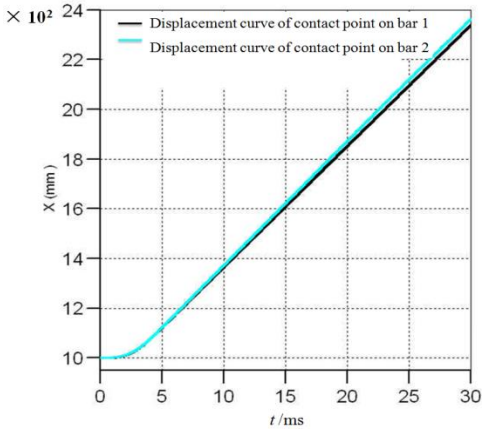

FIGURE 7 Curves of displacement of points at the right side of Bar 1 and the left side of Bar 2 varying the time

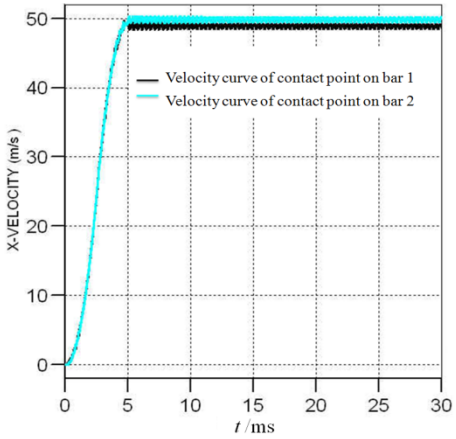

FIGURE 8 Curves of velocity of points at the right side of Bar 1 and the left side of Bar 2 varying the time

As the elastic wave velocity in the bars is:

$$c=\sqrt{\frac{E(1-\mu)}{(1+\mu)(1-2\mu)\rho}}=5859.24 \quad \text{mm/ms}.$$

According to the analysis in section II, we could get the following result by calculation:

$$x_{\text{separation}} > \lambda . \tag{20}$$

Solving the Equation (16) directly is a difficult work, but Equation (20) can be verified indirectly: substituting any $x_{\text{separation}}$ which was smaller than the wavelength λ " in Equation (9) and Equation (15), and solving these equations, we could obtain that $\sigma_{\text{compressive}}$ was always larger than σ_{tensile}. This result means that the compressive stress is always larger than the tensile stress at the contact surface of bar 1 and bar2. So the two bars didn't separate from each other. And this conclusion is consistent with the numerical simulation.

4 Conclusions

On the basis of the basic theory and laws of elastic wave propagation and reflection, stress wave propagation and reflection between two contact elastic bars, one of which was loaded by a triangle wave on the left, has been researched. For three different cases, formulas of separation time and interaction time have been derived. Numerical simulation of these three cases has also been done by using AUTODYN, and comparison of the numerical simulation and the results obtained by the method of this paper showed that the formulas derived here is correct.

Abstract

Using the finite element method solving a class of second order ordinary differential equations, analyses the two-point boundary value problem of a class of second order ordinary differential equations, through numerical examples to validate its effectiveness.

Keywords: ordinary differential equations, finite element method, two-point boundary value problem

1 Introduction

Finite element method (fem) is a calculating method that booming in the 1960's, it has a wide range of applications, such as elasticity related problem [1-2], related problems in fluid mechanics [3], the heat conduction problem [4-5].

Using the finite element method solves the following two-point boundary value problem of second order ordinary differential equations:

$$\begin{cases} Ly := -\frac{d}{dx}(p(x)\frac{du}{dx}) + r(x)(\frac{du}{dx}) + q(x)u = f(x) \quad a < x < b & (1) \\ u(a) = u'(b) = 0 & (2) \end{cases}$$

Among them $p(x) \in C'[a,b], r(x), q(x), f(x) \in C[a,b], p(x) \geq p_{\min} > 0, q(x) \geq 0$.

2 Generalized solution

Through the following method, the equation (3) and equation (1) are equivalent, the solution of original problem is called the classical solution, and solution meet the integral form is called the generalized solution. To determine the generalized solution of the new equation is the starting point of the finite element method (fem).

Use it multiply equation (1) both ends, and find the x integrate on [a, b], using part of the integral, then we can get:

$$-p(x)u'(x)\Big|_{x=a}^{x=b} + \int_a^b p(x)u'(x)\phi'(x)dx + \int_a^b r(x)u'(x)\phi(x)dx + \int_a^b q(x)u(x)\phi(x)dx = \int_a^b f(x)\phi(x)dx.$$

By the boundary conditions (2) and $\phi(a) = 0$, then

$$\int_a^b p(x)u'(x)\phi'(x)dx + \int_a^b r(x)u'(x)\phi(x)dx + \int_a^b q(x)u(x)\phi(x)dx = \int_a^b f(x)\phi(x)dx. \quad (3)$$

Then the $u(x)$ is the general solution of boundary problem (1)-(2).

3 Element subdivision and interpolation

Let $a = x_0 < x_1 < x_2 < \cdots < x_n = b$, element e_i is region $[x_i, x_{i+1}]$, let $u(x_i) = u_i$ in $x = x_i$, u_0 is known, $u_1, \cdots, u_n$ is unknown. In finite element method (fem), when determining the subdivision, determine the specific form of interpolation polynomial on each small unit , and express it through the node function value, that means, in every element e_i , let $u(x) = N_i(x)u_i + M_i(x)u_{i+1} = [N]\{\delta\}e_i, \phi(x) = [N]\{\delta^*\}_{ei}$, and $N_i(x) = \frac{1}{L_i}(x_{i+1} - x), M_i(x) = \frac{1}{L_i}(x - x_i)$ is linear interpolation function.

$L_i = x_{i+1} - x_i, \phi(x)$ is virtual displacement $[N] = (N_i(x), M_i(x)), \{\delta\}_{e_i} = (u_i, u_{i+1})^T$ is nodal displacement in element e_i , $\{\delta^*\}_{e_i} = (u_i^*, u_{i+1}^*)^T$ is node virtual displacement vector in element e_i .

4 Computing units stiffness matrix and load vector

In this paper, the finite element method (fem) is given by specific physical instance and in the engineering, matrix $[K]_{e_i}$ reflects the unit's rigidity, $[K]_{e_i} \cdot \{\delta\}_{e_i} = \begin{pmatrix} -U_i^{e_i} \\ -U_{i+1}^{e_i} \end{pmatrix}$ show that in order to maintain deformation of the unit e_i , two endpoints nodes $x = x_i$, x_{i+1} in unit e_i need external force, to his balance, the two external force is the force

* ***Correspondign author*** e-mail: lzyzhiyanli@163.com

$-U_i^{e_i}$ and $-U_{i+1}^{e_i}$ through node, and the force known as the equivalent nodal force. While unit load vector $\{F\}e_i$ reflects the effect on the unit e_i displacement distribution of physical strength, its each component shows after the displacement the effect on the two end node $x = x_i, x_{i+1}$ of equivalent strength, therefore, at first, we need to calculate the element stiffness matrix.

Rewrite (3) as

$$\sum_{i=0}^{n-1}\int_{e_i}[p(x)u'(x)\phi'(x)+r(x)u'(x)\phi(x)+q(x)u(x)\phi(x)]dx=\sum_{i=0}^{n-1}\int_{e_i}f(x)\phi(x)dx\ . \tag{4}$$

Using u_i, u_{i+1} and $u_i^*, u_{i=1}^*$ represent $\int_{e_i}(pu'\phi'+ru'\phi+qu\phi)dx, \int_{e_i}f\phi dx$. If a number of a is regarded as a matrix of order, we can see $a^T=a$, then

$$\begin{aligned}\int_{e_i}(pu'\phi'+ru'\phi+qu\phi)dx&=\int_{x_i}^{x_{i+1}}(p(\phi')^Tu'+r\phi^Tu'+q\phi^Tu)dx\\&=\int_{x_i}^{x_{i+1}}p([B]\{\delta^*\}_{e_i})^T([B]\{\delta\}_{e_i})dx+\int_{x_i}^{x_{i+1}}r([N]\{\delta^*\}_{e_i})^T([B]\{\delta\}_{e_i})dx+\int_{x_i}^{x_{i+1}}q([N]\{\delta^*\}_{e_i})^T([N][\delta]_{e_i})dx\\&=\{\delta^*\}_{e_i}^T(\int_{x_i}^{x_{i+1}}p[B]^T[B]dx+\int_{x_i}^{x_{i+1}}[N]^T[B]dx+\int_{x_i}^{x_{i+1}}q[N]^T[N]dx)\{\delta\}_{e_i}dx\\&=\{\delta^*\}_{e_i}^T[K]_{e_i}\{\delta\}_{e_i}\end{aligned}\tag{5}$$

$[K]_{e_i}$ is called element stiffness matrix, its concrete form is:

$$\begin{aligned}[K]_{e_i}&=\int_{x_i}^{x_{i+1}}(p[B]^T[B]+[N]^T[B]+q[N]^T[N])dx\\&=\begin{pmatrix}\frac{p_i}{L_i^2}+\frac{r_i}{L_i}\int_{x_i}^{x_{i+1}}N_idx+\int_{x_i}^{x_{i+1}}qN_i^2dx & -\frac{p_i}{L_i^2}+\frac{r_i}{L_i}\int_{x_i}^{x_{i+1}}N_idx+\int_{x_i}^{x_{i+1}}qN_iM_idx\\-\frac{p_i}{L_i^2}+\frac{r_i}{L_i}\int_{x_i}^{x_{i+1}}N_idx+\int_{x_i}^{x_{i+1}}qN_iM_idx & \frac{p_i}{L_i^2}+\frac{r_i}{L_i}\int_{x_i}^{x_{i+1}}N_idx+\int_{x_i}^{x_{i+1}}qM_i^2dx\end{pmatrix}.\end{aligned}$$

Among it, $p_i=\int_{x_i}^{x_{i+1}}p(x)dx$.

Make the element stiffness matrix as $[K]_{e_i}=\begin{pmatrix}k_{i,i}^{e_i} & k_{i,i+1}^{e_i}\\ k_{i+i,i}^{e_i} & k_{i+1,i+1}^{e_i}\end{pmatrix}$, then stiffness coefficient $k_{j,m}^{e_i}$ is

$$k_{i,i}^{e_i}=\frac{p_i}{L_i^2}+\frac{r_i}{L_i}\int_{x_i}^{x_{i+1}}N_idx+\int_{x_i}^{x_{i+1}}qN_i^2dx$$

$$k_{i,i+1}^{e_i}=k_{i+1,i}^{e_i}=-\frac{p_i}{L_i^2}+\frac{r_i}{L_i}\int_{x_i}^{x_{i+1}}N_idx+\int_{x_i}^{x_{i+1}}qN_iM_idx,$$

$$k_{i+1,i+1}^{e_i}=\frac{p_i}{L_i^2}+\frac{r_i}{L_i}\int_{x_i}^{x_{i+1}}N_idx+\int_{x_i}^{x_{i+1}}qM_i^2dx\ . \tag{6}$$

$$\begin{aligned}\int_{e_i}f\phi dx&=\int_{e_i}\phi^Tfdx\\&=\int_{x_i}^{x_{i+1}}([N]\{\delta^*\}_{e_i})^Tfdx=\{\delta^*\}_{e_i}^T\{F\}_{e_i}\end{aligned}$$

$\{F\}_{e_i}$ is called Unit load vector, its concrete form is:

$$\{F\}_{e_i}=\int_{x_i}^{x_{i+1}}[N]^Tfdx=\begin{pmatrix}\int_{x_i}^{x_{i+1}}N_ifdx\\ \int_{x_i}^{x_{i+1}}M_ifdx\end{pmatrix}.$$

Expressed $\{F\}_{e_i}$ as $\{F\}_{e_i}=\begin{pmatrix}F_i^{e_i}\\ F_{i+1}^{e_i}\end{pmatrix}$, then, unit load coefficient is $F_i^{e_i}=\int_{x_i}^{x_{i+1}}N_ifdx, F_{i+1}^{e_i}=\int_{x_i}^{x_{i+1}}M_ifdx$.

5 Total stiffness matrix and the total load vector

Expand $[K]_{e_i}, \{F\}_{e_i}, \{\delta\}_{e_i}$ and $\{\delta^*\}$ for n + 1 order matrix and the n + 1 d vector, put (5) and (6) into (4), then

$$\begin{aligned}&\{\delta^*\}^T(\sum_{i=0}^{n-1}[K]_{e_i})\{\delta\}=\{\delta^*\}^T(\sum_{i=0}^{n-1}\{F\}_{e_i})\\&\{\delta^*\}^T([K]\{\delta\}-\{F\})=0\end{aligned}\ . \tag{7}$$

Among them, $[K]=\sum_{i=0}^{n-1}[K]_{e_i}, \{F\}=\sum_{i=0}^{n-1}\{F\}_{e_i}$ as the total stiffness matrix and the total load vector respectively.

6 Constraint handling

As on the endpoint x = 0, $u(x)$ satisfy the boundary conditions (2), therefore $u_0=0$, in addition $\phi(0)=0$, so

$u_0^* = 0$, and (7) has the form $\left\{\tilde{\delta}^*\right\}^T([\tilde{K}]\{\delta\} - \left\{\tilde{F}\right\}) = 0$, $\left\{\tilde{\delta}^*\right\}$, $\left\{\tilde{F}\right\}$ are respectively after the first element with 0 instead of n+1-dimensional vector in $\left\{\delta^*\right\}$, $\{F\}$, $\left[\tilde{K}\right]$ is the element in the first row and the first column in addition to the diagonal to 1, use 0 instead of the back rest of the n+1 matrix. Due to the arbitrary of $\left\{\tilde{\delta}^*\right\}$, we can obtain:

$$\left[\tilde{K}\right]\{\delta\} = \left\{\tilde{F}\right\}. \tag{8}$$

From the change in the overall stiffness matrix $[K]$ for the first line in the first column elements, forming process of $\left[\tilde{K}\right]$, known as the constraint processing. Main purpose is to require the desires of function satisfy the boundary constraint conditions $u_0 = 0$ on boundaries. After dealing with the constraints, a new overall stiffness matrix $\left[\tilde{K}\right]$ from positive semi-definite to positive definite. In fact, because: $\left\{\tilde{\delta}\right\}^T[K]\{\delta\} = (0, u_1, \cdots, u_n)$ $[K](0, u_1, \cdots, u_n)^T \geq 0$

So $\left[\tilde{K}\right]$ is symmetric positive definite, so a linear equations (8) solution is unique. Because above is our whole process in solving the equation (3), and because equation (3) and equation (1) are equivalent, so here equation (8) is the solution of the original problem (1) what we want.

7 A Numerical example and conclusion

Consider the following second order ordinary differential equation with two-point boundary value problems: $\begin{cases} -(x^2u'(x))' + 2u(x) = 2x^2, 0 < x < 1 \\ u(0) = u'(1) = 0 \end{cases}$.

Compare with equation (1), this example as $p(x) = x^2$, $r(x) = 0$, $q(x) = 2$, $f(x) = 2x^2$, now the interval [0, 1] is divided into four units, the five coordinates of nodes are $x_0 = 0, x_1 = \frac{1}{4}, x_2 = \frac{1}{2}, x_3 = \frac{3}{4}, x_4 = 1$ respectively.

Stiffness matrix:

$$[K]_{e_i} = \begin{pmatrix} 4(x_{i+1}^2 - x_{i+1}x_i + x_i^2) & \frac{4}{3}(x_{i+1}^2 + x_i^2) - \frac{20}{3}x_{i+1}x_i \\ \frac{4}{3}(x_{i+1}^2 + x_i^2) - \frac{20}{3}x_{i+1}x_i & 4(x_{i+1}^2 - x_{i+1}x_i + x_i^2) \end{pmatrix}.$$

Unit load vector:

$$[F]_{e_i} = \begin{pmatrix} \frac{2}{3}x_{i+1}(x_{i+1}^2 + x_{i+1}x_i + x_i^2) - \frac{1}{2}(x_i + x_{i+1})(x_i^2 + x_{i+1}^2) \\ \frac{1}{2}(x_i + x_{i+1})(x_i^2 + x_{i+1}^2) - \frac{2}{3}x_{i+1}(x_{i+1}^2 + x_{i+1}x_i + x_i^2) \end{pmatrix}.$$

The overall stiffness matrix is $[K] = \sum_{i=0}^{3}[K]_{e_i}$, total load vector is $[F] = \{F\} = \sum_{i=0}^{3}\{F\}_{e_i}$, the exact solution is $u(x) = x - \frac{1}{2}x^2$, the numerical results are shown in Table 1.

TABLE 1 Numerical result

Abstract

In recent years, wireless sensor network had been more and more widely used in our daily life, and with the propose of Monte Carlo localization (MCL) algorithm, node localization of the mobile wireless sensor network had been solved effectively. But it needed to have a large number of samples if it used the Monte Carlo localization algorithm to obtain a high positioning accuracy. This paper proposed a new improved algorithm (iterative Monte Carlo localization algorithm) based on the Monte Carlo localization algorithm. In iterative Monte Carlo localization (IMCL) algorithm, each anchor node location information was forwarded by its neighbour nodes only once and preserved by the receiving node in each period. Then the next period, merge it and the sent/forwarding information into a packet and forward. Make sure that points have more observations for estimating previous location sets. IMCL, meanwhile, also can make full use of observation to filter out some samples that were far from the real position of node, so as to improve the accuracy of node localization. We finally confirmed by experiment: IMCL algorithm had higher positioning accuracy compared with other algorithm.

Keywords: IMCL, immune genetic algorithm, wireless sensor network, improve the accuracy of localization

1 Introduction

Wireless Sensor network (WSNs) has characteristics of self-organization, low cost, low power consumption, and it has broad application prospects in the environmental monitoring, remote medical monitoring, military and other fields. Generally, it is meaningful for monitoring information that the location has been determined. GPS devices can be installed on each sensor node to determine the location information, but it is very expensive. Therefore, the research of wireless sensor network node location technology is of great significance.

In recent years, many scholars at home and abroad devote to the research of node location technology, and put forward many effective algorithm Jennifer Yick [1]. During the process of positioning, according to whether there is need to measure the distance between nodes, node localization algorithm can be divided into two categories:

1) Positioning algorithm based on distance: these algorithms rely on the range information between the nodes of additional hardware measuring, such as the received signal strength (RSSI), the time of arrival (TOA) Kuang Xinghong [2], arrival time difference of the different signal (TDOA) and the signal arrive Angle (AOA). The shortcomings of this method are that the extra range of hardware increases volume and the cost of node.

2) Localization algorithm irrelevant with distance: this kind of algorithm achieves node localization mainly based on the connectivity between the nodes, and localization cost is low. Centroid algorithm is a simple localization algorithm which is irrelevant with distance, unpositioning node takes polygon centroid as its estimate which is composed by its neighbours of beacon nodes. DV - Hop algorithm is typical. In addition, many scholars also explore the positioning method based on the mobile beacon nodes Pubudu N Pathirana [3], Kuo-Feng Su [4], Luo Ji [5].

2 MCL algorithm

2.1 THE INTRODUCTION OF MCL ALGORITHM

In MCL algorithm time is divided into several discrete time periods and suppose that the unpositioning node and beacon nodes do not know their own direction and speed, but their maximum velocity $v_{\max}$ is given. Unpositioning node needs to relocation in each time period. $L_k = \{l_k^0, l_k^1, ..., l_k^{n-1}\}$ means the location of the sample set of unpositioning node at k time. At the beginning, unpositioning node has no any information about the location, so it randomly selects N points to form the initial location of sample set $L_0 = \{l_0^0, l_0^1, ..., l_0^{n-1}\}$ from decorate area. In the following time period, unpositioning node repeats the period of forecast and filtering to implement the position. Take the positioning process at k time for example. In the prediction stage, according to the location

[*]***Corresponding author*** e-mail: cjcaojing@163.com

of sample set at the k–1 $L_{k-1}=\{l_{k-1}^0, l_{k-1}^1, ..., l_{k-1}^{n-1}\}$ and its motion model, unpositioning node randomly collects N samples $L_k=\{(l_k^0)c, (l_k^1)c, ..., (l_k^{n-1})c\}$, namely $(l_k^i)c, (i=0,1,2,...,N-1)$ randomly selects from the circle which is centered in l_{k-1}^i and the radius is $v_{\max}$. In updating stage, unpositioning node uses the observed value $O_k=\{S_1, S_2, ..., D_1, D_2, ...\}$ received at k moment to filter samples that do not satisfy the conditions. S_j and D_j is the position of the beacon nodes of unpositioning node. Suppose receive all the information instantly at k time and the define $d(l_1, l_2)$ is the Euclidean distance between location l_1 and l_2, r is the wireless communication distance of a node. Filter conditions of samples $(l_k^i)c$ are:

$$\begin{matrix} Filter((l_k^i)c)=PS_j, d((l_k^i)c), S_j \\ rCPD_j, r<d((l_k^i)c, D_j)|2r \end{matrix} . \quad (1)$$

If the value of the filter conditions is false, $(l_k^i)c$ will be filtered. In particular, if the distance between $(l_k^i)c$ and jump of the beacon node is greater than r or the distance between $(l_k^i)c$ and two jump beacon node is not between r and 2r, then it means that $(l_k^i)c$ does not comply with the conditions, and should be filtered. On the other hand, $n(l_k^i)c$ should be stayed.

Due to the unfitted samples have been filtered, after filtering stage, there may be not enough samples, unpositioning node repeats prediction and filtering process until the samples are enough. Then, these samples form the location of the sample set $L_k=\{l_k^0, l_k^1, ..., l_k^{n-1}\}$ at k. And take all the sample average as position estimation of unpositioning node at k.

2.2 THE ANALYSIS OF MCL ALGORITHM

According to the positioning process of MCL algorithm, we can deduce that the following two factors may affect the point positioning accuracy of unpositioning node at k.

1) Observations O_k: the direct way to increase the observation is to improve the density of beacon node, but it will increase the cost of system, including hardware cost and communication consumption of beacon nodes. Another common method is to use location information of multiple hops beacon node, but it can lead nodes forwarding packets frequently in each time period to increase the node communication costs. In addition, multiple hops can also cause a large time delay of communication.

2) The location of the sample set L_{k-1} at k–1: if at k–1, the more closer to the actual location of unpositioning node $l_{k-1}^i, (i=0,1,2,...,N-1)$ is at k, the larger the probability that predicting samples $(l_k^i)c$ is close to the node's actual location is. And improve the positioning accuracy of unpositioning node at k.

3 IMCL algorithm

3.1 THE BASIC DEFINITIONS AND SYMBOLS

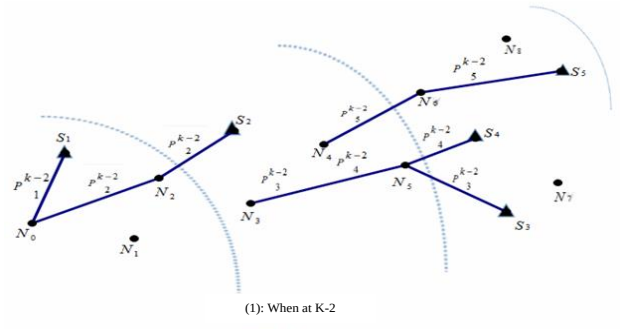
For convenience, this section will illustrate the related definitions and symbols.

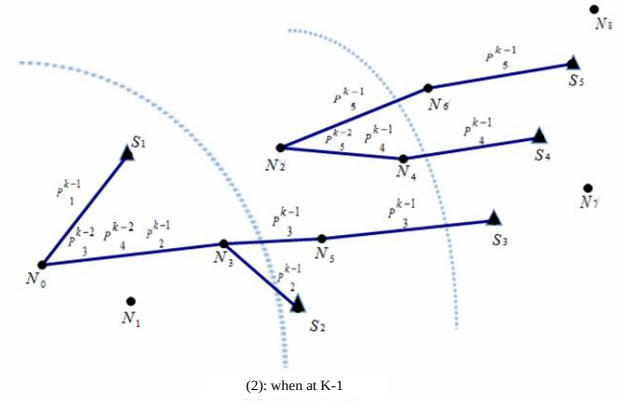
S_i means the beacon node I, i=0,1,2,…. N_i means the unpositioning node I, i=0,1,2,…. S_k^i is the position of beacon node S_i of unpositioning node at k. D_k^i is the position of beacon node S_i of unpositioning node at k. T_{k-1}^i is the position of beacon node S_i of unpositioning node at k–1. However, unpositioning node can receive information at k, but not at k–1; M_{k-1}^i is the position of multiple jumps beacon node S_i of unpositioning node at k–1(l\2). Similarly, the unpositioning node can receive information at k. O_{k-1}^k is the observation of unpositioning node at k which is used to calculate the position sample set at k–1, $l_{k-1}^i|k$ is a sample set during prediction stage, when the unpositioning node at k calculates the position sample set at k–1.

3.2 DESIGN OF ALGORITHM

Firstly, analyse how unpositioning node estimates observations of position sample sets in previous times. As shown in Figure 1, a circle means the moving unpositioning node, triangle means the moving beacon nodes. Linear between nodes means communication link. In order to simplify the graphic, Figure 1 only gives a few typical communication links. The line symbol p_j^t represents the position of the beacon node j at t. It is included in the node packets sent currently. Similar to the MCL algorithm, these packets which include position of beacon node can be forwarded at most once in each segment. However, the node, which receives the packet will save this information, and merge them into momentum/forwarding packets to forward in the next period of time. At k–2, for example, N_2 receives the packets which contains its beacon node location (p_2^{k-2}), and forward the packet immediately. At k–2, N_4 receives the packet which contains its beacon node location (p_5^{k-2}), but N_4 does not forward it immediately. At k–1, N_4 receives the packet which contains its beacon node location (p_4^{k-2}), and then forwards the packet, at this point; N_4 merges p_5^{k-2} into the packets and sends out. Obviously, IMCL algorithm does not increase the packet

number. Of course, the bytes number of each packet will increase. However, through proper fusion technology, we can minimize the number of bytes.





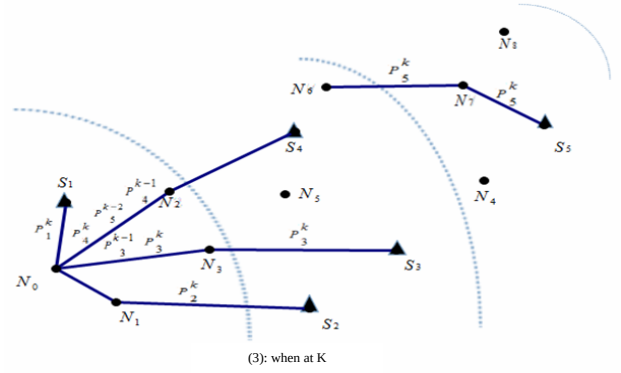


FIGURE 1 The communication link of nodes between k–2 and k, where N_0 is static

According to the analysis of Figure 1, from k–2 to k, the observations of position sample set that the unpositioning node N_0 saves to estimate at k–2 are:

$$\begin{aligned} O_{k-2}^{k-2} &= \left\{S_{k-2}^1, D_{k-2}^2\right\}, \\ O_{k-2}^{k-1} &= \left\{S_{k-2}^1, D_{k-2}^2, T_{k-2}^3, T_{k-2}^4\right\}, \\ O_{k-2}^{k} &= \left\{S_{k-2}^1, D_{k-2}^2, T_{k-2}^3, T_{k-2}^4, M_{k-2}^5\right\}. \end{aligned} \tag{2}$$

It shows that unpositioning node can obtain more observations of position sample set of k-i at k-j than at k-s. According to the analysis of the influence factors 1 in the section 2.2, the result of position sample set of k-i at k-j is better than at k-s. At k, therefore, it is necessary for unpositioning node to recalculate the periods location of the sample set to get a better L_{k-1}. At the same time, IMCL refers to MCB algorithm in order to collect better samples during forecast period. The definition $L_{t'}^{t}$ is the position sample set of t_c that is calculated by unpositioning set at t. Figure 2 is the flow diagram of IMCL algorithm. Consider unpositioning node reiterate location of the sample set of previous n–1 times at k, then L_k^k can be got from the process of n MCB iterative calculation, namely:

$$\begin{aligned} L_{k-n+1}^k &= MCB\left\{L_{k-n}^{k-1}, O_{k-n+1}^k\right\}, \\ L_{k-n+2}^k &= MCB\left\{L_{k-n+1}^k, O_{k-n+2}^k\right\}, \\ L_{k-n+3}^k &= MCB\left\{L_{k-n+2}^k, O_{k-n+3}^k\right\}, \\ L_{k-1}^k &= MCB\left\{L_{k-2}^k, O_{k-1}^k\right\}, \\ L_k^k &= MCB\left\{L_{k-1}^k, O_k^k\right\}. \end{aligned} \tag{3}$$

The average of all samples in L_k^k are the estimated position of the unpositioning node at k.

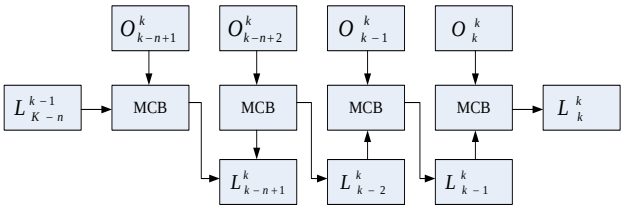

FIGURE 2 The diagram of IMCL algorithm

3.3 THE FILTERING CONDITIONS

In order to make full use of the observed value, we need to complete the filtering conditions of MCL and MCB algorithm. In IMCL, observation O_{k-1}^k contains four types of beacon node location: S_{k-1}^i, D_{k-1}^i, T_{k-1}^i and M_{k-1}^i. Therefore, in the process of each MCB, prediction sample $l_{k-i}^{i'} \mid k$ has four corresponding filter conditions:

$$filter1\left(l_{k-i}^{i'} \mid k\right) = PS_{k-1}^i \mid O_{k-1}^k, d\left(l_{k-1}^{i'} \mid k, S_{k-1}^i\right) \mid r, \tag{4}$$

$$filter2\left(l_{k-i}^{i'} \mid k\right) = PD_{k-1}^i \mid O_{k-1}^k, r < d\left(l_{k-1}^{i'} \mid k, D_{k-1}^i\right) \mid 2r, \tag{5}$$

$$\begin{aligned} &filter3\left(l_{k-i}^{i'} \mid k\right) = PT_{k-1}^i \mid O_{k-1}^k, \\ &2r < d\left(l_{k-1}^{i'} \mid k, T_{k-1}^i\right) \mid 2r + 2v_{\max}, \end{aligned} \tag{6}$$

$$filter4\left(l_{k-i}^{i'} \mid k\right) = PM_{k-1}^{i} \mid O_{k-1}^{k},$$
$$2r < d\left(l_{k-1}^{i'} \mid k, M_{k-1}^{i}\right). \quad (7)$$

In addition, the movement distance of the nodes within a period of time is not more than $v_{\max}$. This means that if N_j and S_i are not neighbor nodes k–l–1, but are neighbor nodes in k–l, then the distance between them is between r–$v_{\max}$ and r in k–l. On the contrary, the distance between them should be between r-v_{max} and r+v_{max}. This type of filtering is called Motion on Boundary, which can be written as the following form:

$$filter5\left(l_{k-i}^{i'} - 1 \mid k\right) = PS_{k-1}^{i} \mid O_{k-1}^{k} CS_{k-1}^{i} \mid O_{k-1}^{k},$$
$$r - 2v_{\max} < d\left(l_{k-1}^{i'} \mid k, S_{k-1}^{i}\right) \mid r, \quad (8)$$

$$filter6\left(l_{k-i}^{i'} - 1 \mid k\right) = PS_{k-l-1}^{i} \mid O_{k-l-1}^{k} CS_{k-1}^{i} \mid O_{k-1}^{k},$$
$$r - v_{\max} < d\left(l_{k-1}^{i'} \mid k, S_{k-l-1}^{i}\right) \mid r + v_{\max}, \quad (9)$$

So the filtering conditions of prediction sample $l_{k-1}^{i'} \mid k$ are:

$$Filter\left(l_{k-1}^{i'} \mid k\right) = Filter1\left(l_{k-1}^{i'} \mid k\right) C,\ filter6\left(l_{k-1}^{i'} \mid k\right). \quad (10)$$

We find that T_{k-1}^{i} and M_{k-1}^{i} may be useless O_{k-1}^{i}. Because node is random in movement speed and direction will lead nodes cannot be connected in a certain period of time. In k-l, for example, the distance between S_i and N_i is between r and 2r, but they lack a rely node, so N_l can't get the location information of S_i at a time of k-l, but can receive this information at the time of k, namely T_{k-1}^{i} or M_{k-1}^{i}. The process according to the sub-conditions of filter 3 or 4 is clearly not appropriate. Although the probability is low, in order to make more precise positioning process, in IMCL algorithm, set a limit. If the number of filtering prediction sample which does not meet filter3 or filter4 is more than the limit value, then remove T_{k-1}^{i} or M_{k-1}^{i} from O_{k-1}^{i}.

4 The simulated analysis

According to IMCL algorithm, we extend the MCL simulator. This section uses extended simulator to test the performance of IMCL algorithm. All nodes randomly distributed in a 500 m @ 500 m square area, and the communication radius of beacon node and unpositioning node is 50 m, the density of unpositioning node (the average number of neighboured node), number of samples are 10 and 50 respectively. We analyse the IMCL algorithm from several aspects:

1) With the change of time, the positioning error of different MCL algorithm.

2) Research the influence of beacon node density S_d to the positioning accuracy. In the rest tests, the density of beacon node is fixed, that is S_d=1.

3) Research the influence of the node maximum speed $v_{\max}$ to the positioning performance. In the rest tests, set $v_{\max}$=0.2r.

4) Analyse the influence of iterations n to the positioning accuracy and processing time. In other tests, get n=6.

All the simulation results are got from the average of 20 times independent experiments. Positioning error is the ratio between absolute positioning error and the radius of wireless communication. The average position error is the average of positioning error of all unpositioning nodes. In particular, the average positioning error of k3.2~k3.4 is measured in the stable stage of position.

4.1 POSITIONING ERROR

Figure 3 is the average positioning error curve of different MCL algorithm. During the positioning initialization phase, the average position error between IMCL and MCB is close; however, as time goes on, IMCL achieves better location performance. In the end, all MCL algorithm can achieve a stable state, i.e. the average positioning error fluctuates in a small scope. In stable phase, compared with the MCL and MCB, the average positioning error of IMCL algorithm has fallen about 40% and 40% respectively.

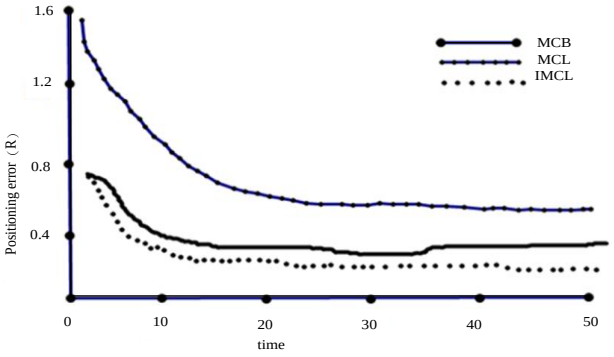

FIGURE 3 The average positioning error of different MCL $(S_d = 1, V_{\max} = 0.2x, n = 6)$

4.2. THE DENSITY OF BEACON NODE

Increase the density of beacon node can improve positioning accuracy, but also increase the network cost and energy consumption of communication. As the change of S_d, the average position error of different MCL algorithm is shown in Figure 4. With the increase of S_d, positioning accuracy of all MCL algorithms is increased, because the unpositioning node can obtain more observations. But it is worth noting that the increase of S_d has large influence on positioning accuracy of the MCL and MCB. In particular, when S_d is greater than 1.5, the average positioning error of IMCL is close to MCB. For how to get more observations is one of the inspired factors

of IMCL algorithm, so if the S_d is too high, there will exist redundant observation. This shows that under the condition of the low density of beacon node, IMCL algorithm has more advantages.

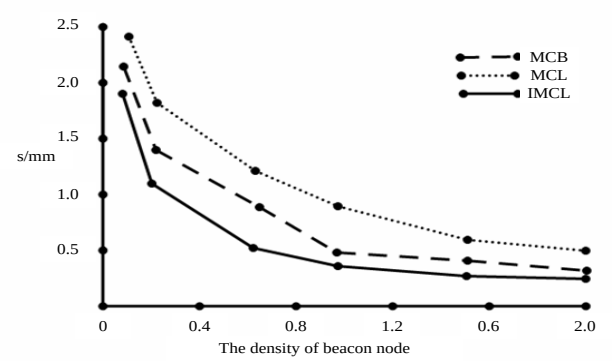

FIGURE 4 The influence of beacon node density to the positioning accuracy $(V_{\max}=0.2r, n=6)$

4.3 THE MAXIMUM SPEED OF NODE

Figure 5 is the average position error curve of different MCL algorithm with the change of v_{max}. Pending a node and beacon node's actual speed is uniformly distributed in the interval [0, v_{max}], so the node's average speed is proportional to the v_{max}. From the diagram, we can see that along with the increase of v_{max}, the difference of the average position error between IMCL with MCB (MCL) decreases. Because v_{max} affects the positioning process from two aspects. First of all, in the prediction stage, the sample is selected from the circle which is centred on l_{t-1}^{i} and the radius is v_{max}, so the increase of v_{max} will cause a decline in the accuracy of the sample collection. The negative effect on all MCL algorithms is same. In each time period, on the other hand, the greater the average speed of nodes is, the more observed values received are, which can filter out more samples do not comply with the conditions. However, one of the key technologies of IMCL algorithm is to make full use of the observed value to filter out worse samples, so the positive effect is not obvious.

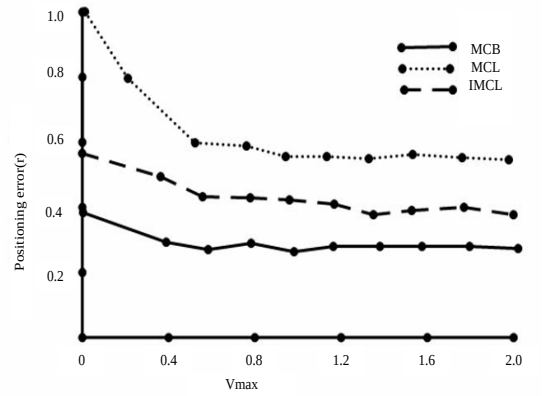

FIGURE 5 The influence of node maximum speed on the positioning accuracy

4.4 ITERATIONS

Change the number of iterations n, the average position error and the average processing time of IMCL (in each time period of the positioning process, the time of performing prediction and update phase) are shown in Figures 6 and 7 respectively. With the increase of the number of iterations, the positioning accuracy has improved, the processing time also increases. However, when the number of iterations reaches to a certain value, the number of iterations has less influence on positioning accuracy. Therefore, by adjusting the number of iterations cans the keep the relationship between the positioning accuracy and the processing time required balance. In addition, we can find an interesting result from Figure 7: the required processing time when the number of iterations is 1 is longer than that when the number of iterations is 2. Because when n=1, IMCL algorithm degenerates into MCB algorithm. In MCB algorithm, the accuracy of position of sample set in predict phase is low, so after filtering stage, reserved samples is less, leading that we have to constantly perform re-sampling/update process in place to ensure that there is enough samples.

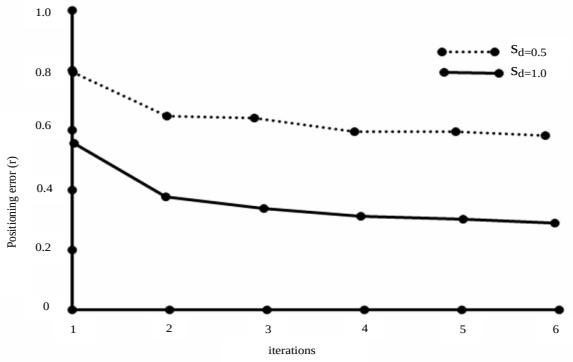

FIGURE 6 The influence of iterations on positioning accuracy $(V_{\max}=0.2r)$

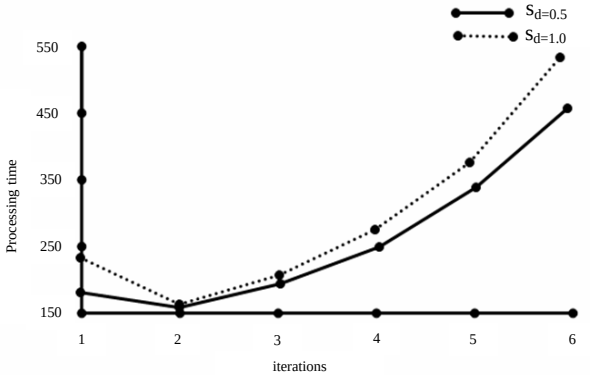

FIGURE 7 The relationship between iterations and processing time $(V_{\max}=0.2r)$

5 Conclusion

Based on the MCL positioning technology of mobile wireless sensor network, this paper puts forward an iterative Monte Carlo localization algorithm. Use extension MCL simulator to process simulation experiments, and analyse algorithm performance from beacon node density, node maximum velocity, number of iterations, etc. The simulation results show that compared with the MCB and MCL, IMCL algorithm is better in performance. In particular, when beacon node density is lower, the superiority of IMCL algorithm can be better reflected. In addition, by adjusting the number of iterations can keep the relationship between the positioning accuracy and the processing time required balance.

Abstract

Determining optimum cluster number is a key research topic included in cluster validity, a fundamental problem unsolved in cluster analysis. In order to determine the optimum cluster number, this article proposes a new cluster validity function for two-dimension datasets theoretically based on geometric probability. The function makes use of the corresponding relationship between a two-dimension dataset and the related two-dimension discrete point set to measure the cluster structure of the dataset according to the distributive feature of the point set in the characteristic space. It is designed from the perspective of intuition and thus easily understood. Through TM remote sensing image classification examples, compare with the supervision and unsupervised classification in ERDAS and the cluster analysis method based on geometric probability in two-dimensional square, which is proposed in literature 2. Results show that the proposed method can significantly improve the classification accuracy.

Keywords: Cluster validity, Geometric probability, optimum cluster number

1 Introduction

Clustering is an important method of multivariate statistical analysis; it is also an irreplaceable analysis tool in data mining and is widely applied in various research projects [1]. Complete cluster analysis includes: (1) clustering trend analysis; (2) clustering structure extraction; (3) clustering results evaluation. The task of clustering trend analysis is to determine whether a given data set has clustering structure. Clustering structure extraction is a narrow cluster analysis, is the process of applying some algorithm to get the clustering results. Clustering results evaluation is to determine the rationality of clustering results by some standards, whether the clustering results (including levels of classes, the number and the boundaries of classes on each level) are consistent with the clustering structure in the data set. It is also known as cluster validity. Cluster validity function is the basic method to measure the rationality of clustering results [2].

Many clustering structure extraction algorithms have been implemented [3-5], the adapting capabilities of same algorithm for different data sets and different algorithms for same data sets are different, in theory how to evaluate the adapting capabilities of a clustering algorithm and in application how to choose a applicative clustering algorithm for a particular data set is a problem must be solved. For this reason cluster validity is highly valued by scholars, much research focus on it. Currently many literatures preassign a range of optimum cluster number, then use exhaustive method to select the optimum cluster number. It is only fit for the data set that has less data. The method is lack of feasibility in the spatial cluster, which involves huge numbers of the objects (such as remote sensing images' automatic classification). This article proposes and implements a cluster validity function for huge data volume theoretically based on geometric probability [1].

2 Clustering validity classification based on geometric probability

2.1 ANALYTIC EXPRESSION OF THE FUNCTION

Assuming the minimum value and the maximum value of the first term's attribute is x_{min} and x_{max}, respectively; the minimum value and the maximum value of the second term's attribute is y_{min} and y_{max}, respectively, and let:

$$a = Min[(x_{max} - x_{min}), (y_{max} - y_{min})], \quad (1)$$

$$b = Max[(x_{max} - x_{min}), (y_{max} - y_{min})]. \quad (2)$$

Then S is mapped to a discrete point set (still named S) in a rectangular region of a*b. Based on the structural information indicator function and the structural information extraction algorithm about clustering point mode in square region, which is mentioned in reference [13], we design a function to measure the structural information of the point set's geometric distribution by geometric probability.

Do paired connection of n points in this discrete point set S and get a set of line segments: $L(s_i; r_i; \theta_i; i = 1,2,3,...)$, where s_i, r_i, θ_i denote midpoint coordinate, length and angle between vertical axis of the i^{th} line segment in L , respectively, and

* ***Corresponding author*** e-mail: lwticq@163.com

$$0 < r_i \le \sqrt{a^2+b^2}, 0 \le \theta_i \le \pi, i = 1,2,3,\ldots . \tag{3}$$

For L, construct H Function:

$$H(\theta,\Delta\theta,r,\Delta r) = \frac{N}{T} \times \frac{1}{P(\theta,\Delta\theta,r,\Delta r)} . \tag{4}$$

Here, T denotes the total number of line segments in L, and

$$T = C_n^2 = n(n-1)/2 . \tag{5}$$

N denotes the number of the line segments in L, which satisfies:

$$\left[\theta - \frac{\Delta\theta}{2}, \theta + \frac{\Delta\theta}{2}\right] \bigcap \left[r - \frac{\Delta r}{2}, r + \frac{\Delta r}{2}\right]. \tag{6}$$

Function $P(\theta,\Delta\theta,r,\Delta r)$ means the probability of the line segments satisfy

$$\left[\theta - \frac{\Delta\theta}{2}, \theta + \frac{\Delta\theta}{2}\right] \bigcap \left[r - \frac{\Delta r}{2}, r + \frac{\Delta r}{2}\right] \tag{7}$$

in random in rectangle region whose lengths of sides are $a, b(a \le b)$.

Function $H(\theta,\Delta\theta,r,\Delta r)$ means the ratio of the frequency of the number of the line segments in Set L is in the interval

$$\left[\theta - \frac{\Delta\theta}{2}, \theta + \frac{\Delta\theta}{2}\right] \bigcap \left[r - \frac{\Delta r}{2}, r + \frac{\Delta r}{2}\right] \tag{8}$$

and the probability of line segment is in the same interval in completely random.

So we expect

$$E\left[H(\theta,\Delta\theta,r,\Delta r)\right] = 1. \tag{9}$$

If $r = \frac{\sqrt{a^2+b^2}}{2}, \Delta r = \sqrt{a^2+b^2}$, then

$$\begin{aligned} &P(\theta,\Delta\theta,r,\Delta r) \\ &= P(\theta,\Delta\theta,\frac{\sqrt{a^2+b^2}}{2},\sqrt{a^2+b^2}) = U(\theta,\Delta\theta) . \end{aligned} \tag{10}$$

So

$$\begin{aligned} &\int_0^a \int_0^{\pi} A(r,\theta)drd\theta + \int_a^b \int_{\arccos\frac{a}{r}}^{\pi-\arccos\frac{a}{r}} A(r,\theta)drd\theta + \int_b^{\sqrt{a^2+b^2}} \int_{\arccos\frac{a}{r}}^{\arcsin\frac{b}{r}} A(r,\theta)drd\theta \\ &= \frac{1}{3}a^3 + \frac{1}{3}b^3 + ab^2 \ln\frac{\sqrt{a^2+b^2}+a}{b} + a^2 b \ln\frac{\sqrt{a^2+b^2}+b}{a} - \frac{1}{3}(a^2+b^2)\sqrt{a^2+b^2} \end{aligned} , \tag{14}$$

$$\begin{aligned} &\int_{r_1}^{r_2} \int_{\theta_1}^{\theta_2} (b - r\sin\theta)(a - r\cos\theta)drd\theta \\ &= ab(\theta_2-\theta_1)(r_2-r_1) + \frac{1}{6}(r_2^3 - r_1^3)(\sin^2\theta_2 - \sin^2\theta_1) - \frac{1}{2}(r_2^2 - r_1^2)(b\sin\theta_2 - b\sin\theta_1 - a\cos\theta_2 + a\cos\theta_1) . \\ &= M(a,b,r_1,r_2,\theta_1,\theta_2) \end{aligned} \tag{15}$$

$$H(\theta,\Delta\theta,r,\Delta r) = \frac{N}{T} \times \frac{1}{U(\theta,\Delta\theta)} = H(\theta,\Delta\theta) \tag{11}$$

and we expect

$$E\left[H(\theta,\Delta\theta)\right] = 1 . \tag{12}$$

Because the structural information of points set S is stored in Set L, while the points in S gather to multi clusters, the line segments in L must be clustering. It means in completely random the value in some interval is greater than the value. The Figure of $H(\theta,\Delta\theta)$ function will get some peak value in the corresponding interval, the difference between the peak value and 1 indicates the level of clustering, and the number of the peak value indicates the number of clustering directions. A clear corresponding relation exists between the geometric distribution of the points set and the feature of the data set, also exists between Figure of $H(\theta,\Delta\theta)$ function and the structure feature of the point set, so this function is a cluster validity function, which can judge the cluster structure and the validity of clustering results in the data set. The difficulty in process is to derive the analytical expression of $P(\theta,\Delta\theta,r,\Delta r)$ function.

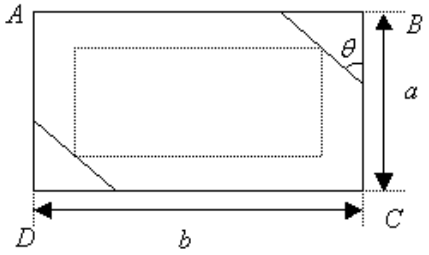

FIGURE 1 The measurement of line segments in the specific intervals and within a rectangle

As shown in Fig.1, if the side lengths of Rectangle $ABCD$ are $a, b(a \le b)$, $P(\theta,\Delta\theta,r,\Delta r)$ indicates the probability of the line segments got from a given rectangle region are in the interval:

$$\left[\theta - \frac{\Delta\theta}{2}, \theta + \frac{\Delta\theta}{2}\right] \bigcap \left[r - \frac{\Delta r}{2}, r + \frac{\Delta r}{2}\right], \tag{13}$$

We measure the total of the line segment by measuring the area of the region where the points of line segments are included in. For a line segment whose length is $r(0<r\le\sqrt{a^2+b^2})$ and angle between Side CB in positive direction is $\theta(0\le\theta\le\pi)$, the probability of the line segment is in the Rectangle $ABCD$ is proportional to the area of region where the points of line segments are in(the rectangle with dashed lines in Fig. 4):

$$A(r,\theta)=(a-r|\cos\theta|)(b-r|\sin\theta|). \tag{16}$$

Let

$$r_1=r-\frac{\Delta r}{2},r_2=r+\frac{\Delta r}{2};\theta_1=\theta-\frac{\Delta\theta}{2},\theta_2=\theta+\frac{\Delta\theta}{2}, \tag{17}$$

Then

$$P(\theta,\Delta\theta,r,\Delta r)=P(\frac{\theta_1+\theta_2}{2},\theta_2-\theta_1,\frac{r_1+r_2}{2},r_2-r_1)=P, \tag{18}$$

$$P=\frac{\int_{r_1}^{r_2}\int_{\theta_{\min}}^{\theta_{\max}}A(r,\theta)drd\theta}{\int_0^a\int_0^{\pi}A(r,\theta)drd\theta+\int_a^b\int_{\arccos\frac{a}{r}}^{\pi-\arccos\frac{a}{r}}A(r,\theta)drd\theta+2\int_b^{\sqrt{a^2+b^2}}\int_{\arccos\frac{a}{r}}^{\arcsin\frac{a}{r}}A(r,\theta)drd\theta}. \tag{19}$$

Here

$$\theta_{\min}=f(r_1,r_2)\ge\theta_1,\theta_{\max}=g(r_1,r_2)\le\theta_2. \tag{20}$$

2.2 NUMERATOR VALUE OF THE FUNCTION

If r_1,r_2 are in the interval $[0,a]$, $f(r_1,r_2)=\theta_1,g(r_1,r_2)=\theta_2$,

$$\begin{aligned}&\int_{r_1}^{r_2}\int_{\theta_{\min}}^{\theta_{\max}}A(r,\theta)drd\theta=\int_{r_1}^{r_2}\int_{\theta_1}^{\theta_2}A(r,\theta)drd\theta\\&=\int_{r_1}^{r_2}\int_{\theta_1}^{\theta_2}(a-r|\cos\theta|)(b-r|\sin\theta|)drd\theta\end{aligned}. \tag{21}$$

Note

TABLE 1 The value of numerator in P Function

Angle	the numerator value
$0<\theta_1<\theta_2\le\frac{\pi}{2}$	$M(a,b,r_1,r_2,\theta_1,\theta_2)$.
$0<\theta_1<\frac{\pi}{2}<\theta_2\le\pi$	$M(a,b,r_1,r_2,\theta_1,\frac{\pi}{2})+M(a,b,r_1,r_2,\pi-\theta_2,\frac{\pi}{2})$.
$\frac{\pi}{2}\le\theta_1<\theta_2\le\pi$	$M(a,b,r_1,r_2,\pi-\theta_2,\pi-\theta_1)$

(1) $0\le r_1<r_2\le a$

1. $$\begin{aligned}&\int_{l_1}^{l_2}\int_{\arccos\frac{a}{r}}^{\arcsin\frac{b}{r}}A(r,\theta)drd\theta\\&=\int_{l_1}^{l_2}\int_{\arccos\frac{a}{r}}^{\arcsin\frac{b}{r}}(a-r\cos\theta)(b-r\sin\theta)drd\theta\end{aligned}, \tag{22}$$

$$\begin{aligned}&=abl_2(\arcsin\frac{b}{l_2}-\arccos\frac{a}{l_2})-abl_1(\arcsin\frac{b}{l_1}-\arccos\frac{a}{l_1})+\frac{1}{2}ab^2\ln\frac{l_2+\sqrt{l_2^2-b^2}}{l_1+\sqrt{l_1^2-b^2}}+\frac{1}{2}a^2b\ln\frac{l_2+\sqrt{l_2^2-a^2}}{l_1+\sqrt{l_1^2-a^2}}+\frac{1}{2}b(l_2\sqrt{l_2^2-a^2}-l_1\sqrt{l_1^2-a^2})\\&-\frac{1}{2}(a^2+b^2)(l_2-l_1)-\frac{1}{6}(l_2^3-l_1^3)+\frac{1}{2}a(l_2\sqrt{l_2^2-b^2}-l_1\sqrt{l_1^2-b^2})\\&=L(a,b,l_1,l_2)\end{aligned}, \tag{23}$$

$$\int_{l_1}^{l_2}\int_{\arccos\frac{a}{r}}^{\theta_2}A(r,\theta)drd\theta=\int_{l_1}^{l_2}dr\int_{\arccos\frac{a}{r}}^{\theta_2}d\left[ab\theta-r(b\sin\theta-a\cos\theta)+\frac{1}{2}r^2\sin^2\theta\right]$$

2. $$\begin{aligned}&=(ab\theta_2-\frac{1}{2}a^2)(l_2-l_1)-\frac{1}{2}(b\sin\theta_2-a\cos\theta_2)(l_2^2-l_1^2)+\frac{1}{2}a^2b\ln\frac{l_2+\sqrt{l_2^2-a^2}}{l_1+\sqrt{l_1^2-a^2}}+\frac{1}{2}b(l_2\sqrt{l_2^2-a^2}-l_1\sqrt{l_1^2-a^2}),\\&-\frac{1}{6}\cos^2\theta_2(l_2^3-l_1^3)-ab(l_2\arccos\frac{a}{l_2}-l_1\arccos\frac{a}{l_1})\\&=C(a,b,l_1,l_2,\theta_2)\end{aligned} \tag{24}$$

$$\begin{aligned}&\int_{l_1}^{l_2}\int_{\theta_1}^{\arcsin\frac{b}{r}}A(r,\theta)drd\theta\\&=\int_{l_1}^{l_2}dr\int_{\theta_1}^{\arcsin\frac{b}{r}}d\left[ab\theta-r(b\sin\theta-a\cos\theta)+\frac{1}{2}r^2\sin^2\theta\right]\end{aligned}$$

3. $$\begin{aligned}&=ab(l_2\arcsin\frac{b}{l_2}-l_1\arcsin\frac{b}{l_1})+\frac{1}{2}ab^2\ln\frac{l_2+\sqrt{l_2^2-b^2}}{l_1+\sqrt{l_1^2-b^2}}+\frac{1}{2}a(l_2\sqrt{l_2^2-b^2}-l_1\sqrt{l_1^2-b^2}).\\&-(ab\theta_1+\frac{1}{2}b^2)(l_2-l_1)-\frac{1}{6}\sin^2\theta_1(l_2^3-l_1^3)-\frac{1}{2}(a\cos\theta_1-b\sin\theta_1)(l_2^2-l_1^2)\\&=S(a,b,l_1,l_2,\theta_1)\end{aligned} \tag{25}$$

(2) $a\le r_1<r_2\le\sqrt{a^2+b^2}$

Firstly calculate three integral expression, let $0<a\le l_1<l_2\le\sqrt{a^2+b^2},0\le\theta_1<\frac{\pi}{2},0<\theta_2\le\frac{\pi}{2}$, then

When r is in the interval $\left[a,\sqrt{a^2+b^2}\right]$, $[f(r_1,r_2),g(r_1,r_2)]$ equals to $[\theta_1,\theta_2]\cap\left(\arccos\frac{a}{r},\pi-\arccos\frac{a}{r}\right)$. (26)

Now, calculate the following integral expressions: $\int_a^l\int_{\theta_1}^{\theta_2}A(r,\theta)drd\theta$. So $R(l,\theta_1,\theta_2)=\int_a^l\int_{\theta_1}^{\theta_2}A(r,\theta)drd\theta$.

TABLE 2 The value of $R(l,\theta_1,\theta_2)$

Angle	Value of l_1, l_2	Range of l	Value of $R(l,\theta_1,\theta_2)$
$0<\theta_1<\theta_2<\beta$	$l_1=a/\cos\theta_1$ $l_2=a/\cos\theta_2$	$a<l\le l_1$	$M(a,b,a,l,\theta_1,\theta_2)$
		$l_1<l<l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+C(a,b,l_1,l,\theta_2)$
		$l\ge l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+C(a,b,l_1,l_2,\theta_2)$
$0<\theta_1<\alpha<\beta\le\theta_2\le\frac{\pi}{2}$	$l_1=a/\cos\theta_1$ $l_2=b/\sin\theta_2$	$a<l\le l_1$	$M(a,b,a,l,\theta_1,\theta_2)$
		$l_1<l<l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+C(a,b,l_1,l_2,\theta_2)$
		$l\ge l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+C(a,b,l_1,l_2,\theta_2)+L(a,b,l_2,l)$
$\alpha\le\theta_1\le\beta$ $<\theta_2\le\frac{\pi}{2}$	$a\sin\theta_2-b\cos\theta_1>0$ $l_1=b/\sin\theta_2$ $l_2=a/\cos\theta_1$	$a<l\le l_1$	$M(a,b,a,l,\theta_1,\theta_2)$
		$l_1<l<l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+S(a,b,l_1,l,\theta_1)$
		$l\ge l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+S(a,b,l_1,l_2,\theta_1)+L(a,b,l_2,l)$
	$a\sin\theta_2=b\cos\theta_1$ $l_1=a/\cos\theta_1$ $l_2=b/\sin\theta_2$	$a<l\le l_1$	$M(a,b,a,l,\theta_1,\theta_2)$
		$l\ge l_1=l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+L(a,b,l_2,l)$
	$a\sin\theta_2-b\cos\theta_1<0$ $l_1=a/\cos\theta_1$ $l_2=b/\sin\theta_2$	$a<l\le l_1$	$M(a,b,a,l,\theta_1,\theta_2)$
		$l_1<l<l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+C(a,b,l_1,l,\theta_2)$
		$l\ge l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+C(a,b,l_1,l_2,\theta_2)+L(a,b,l_2,l)$
$\beta<\theta_1<\theta_2\le\frac{\pi}{2}$	$l_1=b/\sin\theta_2$ $l_2=b/\sin\theta_1$	$a<l\le l_1$	$M(a,b,a,l,\theta_1,\theta_2)$
		$l_1<l<l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+S(a,b,l_1,l,\theta_1)$
		$l\ge l_2$	$M(a,b,a,l_1,\theta_1,\theta_2)+S(a,b,l_1,l_2,\theta_1)$

Angle	Value of $R(l,\theta_1,\theta_2)$
$0<\theta_1<\frac{\pi}{2}<\theta_2\le\pi$	$R(l,\theta_1,\frac{\pi}{2})+R(l,\pi-\theta_2,\frac{\pi}{2})$
$\frac{\pi}{2}\le\theta_1<\theta_2\le\pi$	$R(l,\pi-\theta_2,\pi-\theta_1)$

The value of $R(l,\theta_1,\theta_2)$ is shown as Table 2, and $\alpha=\arccos\frac{a}{b},\beta=\arccos\frac{a}{\sqrt{a^2+b^2}}$.

When $a\le r_1<r_2\le\sqrt{a^2+b^2}$, the value of numerator is $R(r_2,\theta_1,\theta_2)-R(r_1,\theta_1,\theta_2)$.

3) $0\le r_1\le a\le r_2\le\sqrt{a^2+b^2}$

The numerator value is:

$$\int_{r_1}^{r_2}\int_{\theta_1}^{\theta_2}A(r,\theta)drd\theta=\int_{r_1}^{a}\int_{\theta_1}^{\theta_2}A(r,\theta)drd\theta+\int_{a}^{r_2}\int_{\theta_1}^{\theta_2}A(r,\theta)drd\theta=\int_{r_1}^{a}\int_{\theta_1}^{\theta_2}A(r,\theta)drd\theta+R(r_2,\theta_1,\theta_2). \quad (27)$$

3.2 CLUSTERING RESULTS AND COMPARATIVE ANALYSIS

Figure 2 is a synthetic false colour remote sensing images based on the TM data of Band 5, 4 and 3. After the clustering with our proposed algorithm, there are seven categories, including residential areas, shadows, close planting is, dilute vegetation, water, Cho and dry land (Shown as Figure 3).

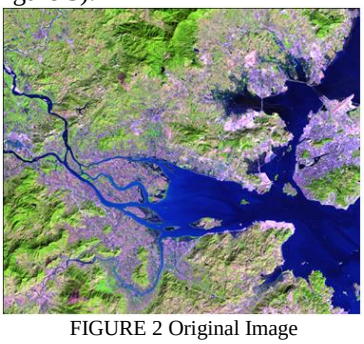

FIGURE 2 Original Image

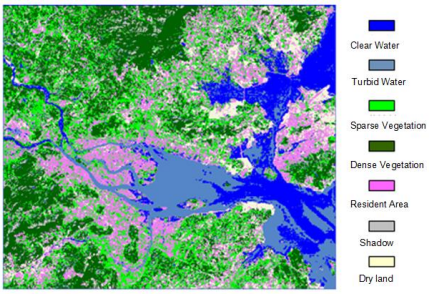

FIGURE 3 Classification Results

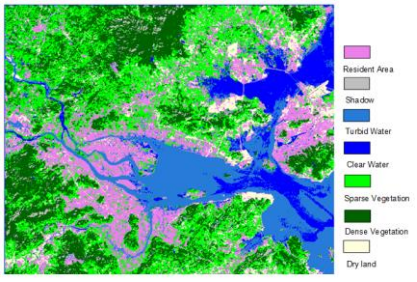

FIGURE 4 clustering results of literature

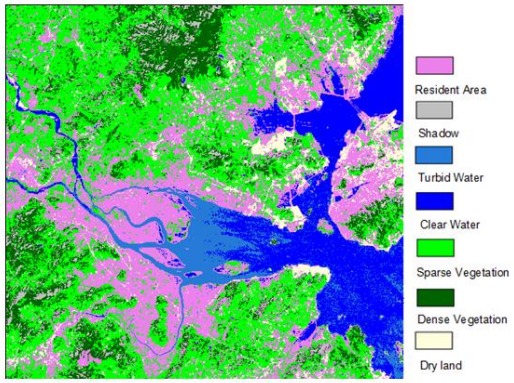

FIGURE 5 results of supervised classification

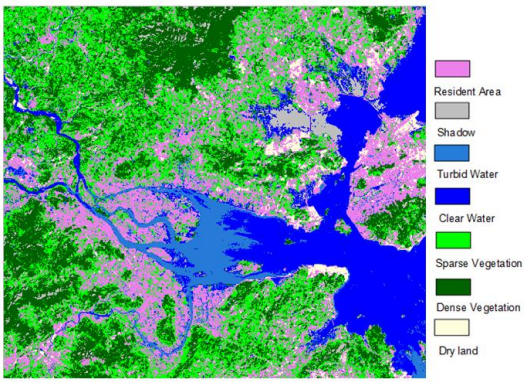

FIGURE 6 Results of Unsupervised Classification

According to the clustering results (Shown as Figure 4) of literature [2] and ERDAS, we conduct supervised classification and unsupervised classification to the same image separately. We pick up 250 pixels in the classification results to accuracy assessment, and compare with the clustering results of literature [2]. Upon examination, specific classification results of four clustering methods are shown as table 1, table 2, table 3 and table 4. The clustering methods include ERDAS supervised classification, ERDAS unsupervised classification, clustering method of literature [2] and clustering method of this paper. Bold figures in the table indicate the number of correct classification pixels for each class. Then calculate classification accuracy and the specific quantitative indicators using the figures in the four tables, results are shown in paper [1].

The paper [1] shows that the classification accuracy of the cluster validity method based on geometric probability is 85.20%, while the classification accuracy of the method, supervised classification and unsupervised classification, which are used in literature [2] are 81.60%, 62.80% and 58.00%, so this cluster validity classification method based on geometry probability is superior to the methods in literature [2].

4 Conclusions

According to the basic idea and clustering steps of geometric probability-based classification method of cluster validity, we select 1498 × 1281 pixels of Xiamen Jiulong River TM images in 2002 Winter, evaluate and compare the clustering results with the supervised classification and unsupervised classification results by ERDAS of the same image. Experimental results show that the classification method of cluster validity based on geometric probability is superior to the literature [2], and it is also superior to the methods of supervised classification and unsupervised classification.

Abstract

Mining frequent itemsets from uncertain transaction dataset is a research topic in data mining. Some algorithms are based on FP-Growth, but they construct the tree structure in a manner that cannot be as compact as the original FP-Tree, so the tree is easily developed to huge size and this hinders their performance. In this paper, we propose a new tree structure called IT-Tree (Itemset Tail-node Tree) to efficiently maintain probability information of itemsets in tail-nodes; we also propose a corresponding algorithm IT-Mine to mine frequent itemsets from IT-Tree without additional dataset scans. We evaluate our approach on real sparse and dense datasets with different minimum support numbers that can produce non-null frequent k-itemsets ($k \geq 2$); the results show that IT-Mine outperforms other algorithms in terms of execution time, especially for large dataset or small minimum expected support number.

Keywords: frequent itemset, frequent pattern, uncertain transaction dataset, data mining

1 Introduction

Uncertain transaction dataset describes the existential probability of each item in a transactional process. Many applications create uncertain datasets; for example, as indicated by [1,2] and [3], measurement errors of RFID, GPS and other sensors are part of the major sources of uncertain data, because the sensor readings are constantly fluctuating and can hardly be precise, such as the location of an object provided by RFID or GPS. Another kind of uncertainty comes from statistical laws; for example, in medical field, the illness or disease diagnosed for a patient cannot be completely determined by one or more symptoms; in market analysis, customer purchase behaviours, computed from basket data for predicting what a customer will buy in the future, are also statistical probabilities [4, 5]. With the development of applications using uncertain datasets, the issue of data mining over uncertain dataset has become a hot topic in data mining in recent years [4-12].

Table 1 shows an example of an uncertain transaction dataset. Each transaction in Table 1 represents that a customer buy a certain item with a probability. The decimal value associated with an item is called the existential probability of the item. For instance, the first transaction T_1 in Table 1 shows that the customer *A* might purchase products "a", "b", "c" and "d" with 60%, 20%, 30% and 50% chances in the future, respectively. The probability values in Table 1 may be obtained from the analysis of the customers' browsing online-shop history: if customer *A* visited an online-shop ten times in a certain period of time, out of which "a" product was clicked six times, then it might be established that customer *A* has a 60% probability to buy "a" in the future. The probability values may also be obtained from data mining results on the supermarket basket data.

TABLE 1 An example of uncertain transaction dataset

TID	Customer	Transaction itemset
T_1	*A*	(a: 0.6), (b: 0.2), (c: 0.3), (d,0.5)
T_2	*B*	(a: 0.7), (e: 0.25), (d,0.8)
T_3	*C*	(a: 0.3), (c: 0.8) ,(d,0.4)
T_4	*D*	(c: 0.7), (e: 0.2), (d,0.3)
T_5	*E*	(a: 0.5), (b: 0.3), (e: 0.3)

Mining frequent itemsets from uncertain transaction dataset is to discover those itemsets whose sum of probability values or occurring probability exceeds the user specified threshold. Because of its probablistic nature, frequent itemsets mining on uncertain transaction dataset is different from that on precise dataset, which has already been well defined and studied [13, 14], and many algorithms have been proposed, such as Apriori [13], FP-Growth [14], MAFIA [15], COFI [16], Pincer-search [17], CHARM [18], Index-BitTableFI [19] etc. Researchers usually extrapolate the existing algorithms on precise data to get their new algorithms on uncertain data. The papers [5, 7, 10-12] proposed algorithms based on Apriori. These algorithms bear the same bottleneck as Apriori: the generating & processing of the candidate itemsets. And with the increasing of the number of long transactions and the decreasing of the minimum expected support, their performance deteriorates rapidly. The algorithms proposed in papers [6,8,9] are based on FP-Growth; in building their UF-Tree, two items with the same name but different existential probabilities are considered as different nodes; this approach leads to excessive memory requirement to maintain the tree.

[*] ***Corresponding author's*** e-mail: seawan@163.com

Our approach is also inspired by FP-Growth, and tries to amend the defects of the above tree-based algorithms: we propose a more efficient tree structure, named IT-Tree (Itemset Tail-node Tree), to maintain the probability information of transaction itemsets, and give an algorithm, named IT-Mine, to mine frequent itemsets from the IT-Tree. An IT-Tree is created by two scans of the dataset, and IT-Mine mines frequent itemsets from the IT-Tree without additional scan of the dataset, and without generating candidate itemsets.

1.1 CONTRIBUTIONS OF THIS PAPER

1) A tree structure named IT-Tree is proposed for maintaining transaction itemsets of an uncertain dataset.
2) An algorithm named IT-Mine is proposed for discovering frequent itemsets from uncertain dataset based on IT-Tree.
3) Both real and synthetic datasets are used in our experiments to evaluate the performance of the proposed algorithm with the state-of-the-art algorithm MBP.

1.2 THE CONSTRUCTION OF THIS PAPER

The rest of this paper is organized as follows: Section 2 is the description of the problem and definitions; Section 3 is related works; Section 4 is our proposed algorithm IT-Mine; Section 5 is the experimental results; and Section 6 is the conclusion and discussion.

2 Problem definitions

An uncertain transaction dataset $D=\{T_1,T_2,\ldots,T_n\}$ contains n transaction itemsets and m distinct items i.e. $I=\{i_1,i_2,\ldots,i_m\}$, and each transaction itemset T_d ($1\le d\le n$) is represented as $\{i_1:p_1, i_2:p_2,\ldots, i_v:p_v\}$ or $\{\{i_1,i_2,\ldots,i_v\},\{p_1,p_2,\ldots,p_v\}\}$, where $\{i_1,i_2,\ldots,i_v\}$ is a subset of I, and p_u is the probability of the item i_u ($1\le u\le v$) in transaction itemset T_d. An itemset $X=\{i_1,i_2,\ldots,i_k\}$ is called a k-itemset, and k is the length of the itemset X.

We adopt definitions similar to those presented in the previous works [5, 11, 13].

Definition 1: According to the paper [13], the *support number* (*sn*) of an itemset X is the number of transaction itemsets containing X.

Definition 2: The probability of an item i_r in transaction itemset T_d is denoted as $p(i_r,T_d)$, and is defined by

$$p(i_r,T_d)=p_r. \tag{1}$$

For example, in Table 1, $p(\{a\},T_1)=0.6$, $p(\{d\},T_1)=0.5$.

Definition 3: The probability of an itemset X in a transaction itemset T_d is denoted as $p(X,T_d)$, and is defined by

$$p(X,T_d)=\prod_{i_r\in X, X\subset T_d} p(i_r,T_d). \tag{2}$$

For example, in Table 1, $p(\{a,d\},T_1)=0.6\times0.5=0.3$, $p(\{a, d\},T_2)=0.7\times0.8=0.56$, $p(\{a, d\},T_3)=0.3\times0.4=0.12$.

Definition 4: The *expected support number* (*exp*) of an itemset X in an uncertain transaction dataset is denoted as $E(X)$, and is defined by

$$E(X)=\sum_{T_d\in D} P(X,T_d). \tag{3}$$

For example, in Table 1, $E(\{a, d\})=p(\{a, d\},T_1)+p(\{a, d\},T_2)+p(\{a, d\},T_3)=0.3+0.56+0.12=0.98$.

Definition 5: According to the probability theory, the occurring probability of the itemset X occurring in k mutually independent transaction itemsets ($0\le k\le|D|$) is denoted as $P_k(X)$, and is defined by

$$P_k(X)=\sum_{S\subseteq D,|S|=k}\left(\prod_{T_d\in S} P(X,T_d)\cdot\prod_{T_d\in D-S}(1-P(X,T_d))\right). \tag{4}$$

For example, in Table 1,

$$\begin{aligned}P_2(\{a,d\})=&p(\{a,d\},T_1)\times p(\{a,d\},T_2)\times\\&(1-p(\{a,d\},T_3))+p(\{a,d\},T_1)\times p(\{a,d\},T_3)\times\\&(1-p(\{a,d\},T_2))+p(\{a,d\},T_2)\times p(\{a,d\},T_3)\times\\&(1-p(\{a,d\},T_1))=0.21072;\end{aligned}$$

$$P_3(\{a,d\})=p(\{a,d\},T_1)\times p(\{a,d\},T_2)\times p(\{a,d\},T_3)=0.02016.$$

Definition 6: According to the probability theory, the occurring probability of the itemset X occurring in more than k mutually independent transaction itemsets ($0\le k\le|D|$) is denoted as $P_{\ge k}(X)$, and is defined by

$$P_{\ge k}(X)=\sum_{S\subseteq D,|S|\ge k}\left(\prod_{T_d\in S} P(X,T_d)\cdot\prod_{T_d\in D-S}(1-P(X,T_d))\right). \tag{5}$$

For example, in Table 1,

$$P_{\ge2}(\{a,d\})=P_2(\{a,d\})+P_3(\{a,d\})+P_{\ge4}(\{a,d\})=0.21072+0.02016+0=0.23088.$$

Note $P_{\ge4}(\{a,d\})$ is 0 because there is only 3 transaction itemsets containing the itemset $\{a,d\}$.

3 Related work

The approaches of finding frequent itemsets from precise dataset can be classified into two categories: the level-wise approach and the pattern-growth approach. The algorithms Apriori [13] and FP-Growth [14] are representative ones for mining frequent itemsets from precise transaction dataset, and they are representative ones for the level-wise approach and pattern-growth approach, respectively. Apriori is to iteratively generate frequent (k+1)-itemsets using frequent k-itemsets ($k\ge1$):

1) a (k+1)-itemset X is a candidate itemset if its k sub k-itemsets are frequent itemsets;

2) the support number of X is calculated by one scan of dataset if X is a candidate itemset;

3) the itemset X is frequent if its support number is not less than the specified minimum support number.

One advantage is that it has a high time performance when the dataset is sparse, does not contain many long transaction itemsets, and the minimum support number is not small. Its main shortcoming is that it requires multiple scans of dataset, and generating candidate itemsets. Pattern-growth also employs the iteration approach:

1) it finds the set of frequent 1-itemsets (the set is denoted as F) under the condition of a k-itemset X ($k \geq 1$),

2) any itemset $X \cup f$ ($f \in F$) is a frequent (k+1)-itemset. It maintains all transaction itemsets on a tree by one scan of dataset, and generates a conditional sub-tree for each frequent itemset X. Thus, it will find all frequent itemsets under the condition of X by scanning this conditional sub-tree, instead of scanning the whole dataset.

An important difference between precise and uncertain transaction dataset is that each transaction itemset of the former only contains items, and that of the latter contains items and their existential probabilities. Thus, the existing algorithms of mining frequent itemsets from precise dataset cannot be used directly on uncertain transaction dataset. Recently, some algorithms have been proposed for mining frequent itemsets from uncertain transaction dataset.

U-Apriori [7] was proposed in 2007 to find frequent itemsets from uncertain transaction dataset, and it was a level-wise approach. The difference of U-Apriori and Apriori is that U-Apriori calculates the sum of probability of a candidate itemset/item X in all transaction itemsets while Apriori calculates the number of transaction itemsets containing X when they scan a dataset to judge whether the candidate itemset/item X is frequent. U-Apriori and Apriori have the same advantage and disadvantage. The time and memory performance may be worse with the increasing of the number of long transaction itemsets and the decreasing of the minimum expected support number.

In 2007, Leung et al. [8] propose a tree-based algorithm, named UF-Growth, for mining frequent itemsets from uncertain transaction dataset using the same definition of frequent itemsets as in paper [7]. UF-Growth is based on FP-Growth, and is a pattern-growth approach. UF-Growth also constructs a UF-Tree using the given uncertain transaction dataset. But, if two items have the same item name but different existential probabilities, they are considered as different items, and they cannot share the same node when they are added to a tree. For example, two sorted itemsets {a:0.90, b:0.70, c:0.73} and {a:0.95, b:0.85, c:0.70}, they will not share the same node "a" because the probabilities of item "a" in two itemsets are different. After the first UF-Tree is built, UF-Growth retrieves the frequent itemsets from the UF-Tree or sub UF-Trees recursively as the method of FP-Growth. However, the UF-Growth algorithm requires a lot of memory to store tree nodes and a large amount of computational time to process tree nodes.

In 2008, Leung et al. [9] proposed two improvements to boost the time and memory performance of UF-Growth. The first improved algorithm uses the idea of the co-occurrence frequent itemset tree [16] to avoid creating of sub UF-Trees. The second improved algorithm considers that the items, which have the same ***k***-digit value after the decimal point, have the same probability. For example, for two sorted itemsets {a:0.90, b:0.70, c:0.73} and {a:0.95, b:0.85, c:0.70}, both probabilities of item "a" are 0.9 and they will share the node "a". When they are inserted to a UF-Tree if k is set as 1; both probabilities of item "a" are 0.90 and 0.95 respectively and they will not share the node "a" if k is set as 2. This improved algorithm has a better performance than its original algorithm UF-Growth. However, the improved algorithm still does not build a UFP-Tree as compact as the original FP-Tree [14], and it may loss some frequent itemsets.

In 2009, Aggarwal et al. [6] proposed the two algorithms UH-mine and UFP-Growth respectively. These two algorithms employ the pattern-growth approach. Aggarwal also performed a comparison on three frequent itemsets mining algorithms U-Apriori, UH-Mine and UFP-Growth, and concluded that U-Apriori outperforms the other two algorithms.

In the papers [6-9], the proposed algorithms are based on the expected support number of an itemset. An itemset, whose *expected support number* is not less than the *user specified minimum expected support number*, is called as a frequent itemset.

In 2008, Zhang et al. [12] proposed an approximate algorithm for mining frequent itemsets from uncertain transaction dataset based on Definition 6, which defines an itemset to be a frequent itemset if its occurring probability is not less than the *user specified minimum probability*.

In 2009, Bernecker et al. [5] developed a dynamic-programming-based algorithm based on Definition 6, to mine frequent itemsets from uncertain transaction dataset, which employs the level-wise approach. This algorithm inherits the advantage and disadvantage of Apriori.

In 2010, Sun et al. [10] proposed algorithms p-Apriori and TODIS to mine frequent itemsets from uncertain transaction dataset. The algorithm p-Apriori is based on Apriori, and applies a divide-and-conquer approach in calculating the occurring probability of an itemset. The difference between TODIS and p-Apriori is that TODIS works in a top-down manner and p-Apriori works in a bottom-up manner. However calculating the occurring probability of an itemset requires a large amount computation, the time performance of the algorithms proposed in the papers [5, 10, 12] is low.

The problem of getting the occurring probability of an itemset is changed to the problem of getting the expected support number of an itemset in the paper [11], because a Poisson binomial distribution can be well approximated by a Poisson distribution [20] and calculating the occurring probability of an itemset requires a large amount computation. The paper [11] also proposed an algorithm MPB based on U-Apriori. MPB can fast identify frequent and non-frequent itemsets from candidate itemsets without scanning the whole dataset; it can achieve a better performance than U-Apriori in terms of time and space. In

this paper, we propose a mining algorithm based on the expected support number of an itemset.

4 Our proposed method

Our proposed algorithm IT-Mine mainly includes two procedures: firstly, create an IT-Tree or sub IT-Tree; secondly, mine frequent itemsets from the IT-Tree or sub IT-Tree. We descript the structure of IT-Tree in Section 4.1, give an example of the construction of IT-Tree in Section 4.2, and describe the process of mining frequent itemsets from the tree with an example in Section 4.3.

4.1 STRUCTURE OF IT-TREE

Definition 7: Let X be a sorted k-itemset $\{i_1, i_2, i_3, \ldots, i_k\}$, where i_k is the *tail-item*. When the itemset X is inserted into a tree T in this order, the node N on the tree that represents this *tail-item* is defined as a *tail-node* for itemset X. The itemset X is called *tail-node-itemset* for node N.

Definition 8: Let an itemset X containing itemset Y be added to a conditional sub-tree T of the itemset Y. On the tree T, the *base probability* of an itemset X is denoted as $BP(X,Y)$, and is defined by

$$BP(Y, X) = P(Y, X). \quad (6)$$

The structure of IT-tree is illustrated in Figure 1. There are two types of nodes on the IT-tree: one is normal node, as shown in Figure 1a, where N records the item name of each node, *Parent* records the parent node, *Children list* records all children nodes; and the other is tail-node, as shown in Figure 1b, where S records support number, *BP* is *base probability* value of a transaction itemsets, and *ItemsP* is an array which records probability values of all items in corresponding *tail-node-itemset*. We use a "list" to maintain *BP* and *ItemsP values* because there may be many itemsets sharing the same tail-node.

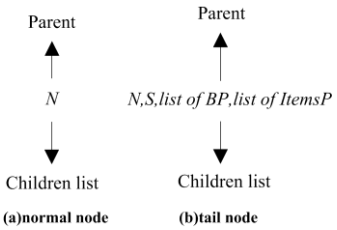

FIGURE 1 Structure of nodes on IT-Tree

4.2 CONSTRUCTION OF AN IT-TREE

The construction of an IT-Tree needs two scans of dataset. In the first scan, create a header table to maintain the support number and expected support of each item; delete those items whose expected support number is less than the user specified *minimum expected support number* from the header table; arrange remaining items of the header table in descending order of support numbers. In the second scan, all transaction itemsets are inserted into an IT-tree. The process is as follows:

1) Delete items that are not in the header table from the transaction itemset;

2) Sort remaining items in the transaction itemset according to the order of the header table;

3) Insert the modified transaction itemset into an IT-tree, and store support number and probability value of each item in each modified transaction itemset to the tail-node of the itemset.

To facilitate tree traversals, *links* in the header table are also maintained (not shown in the Figure 2 for simplicity).

For example, consider the transaction dataset in Table 1. Here the user specified *minimum expected support number* is set to 0.8.

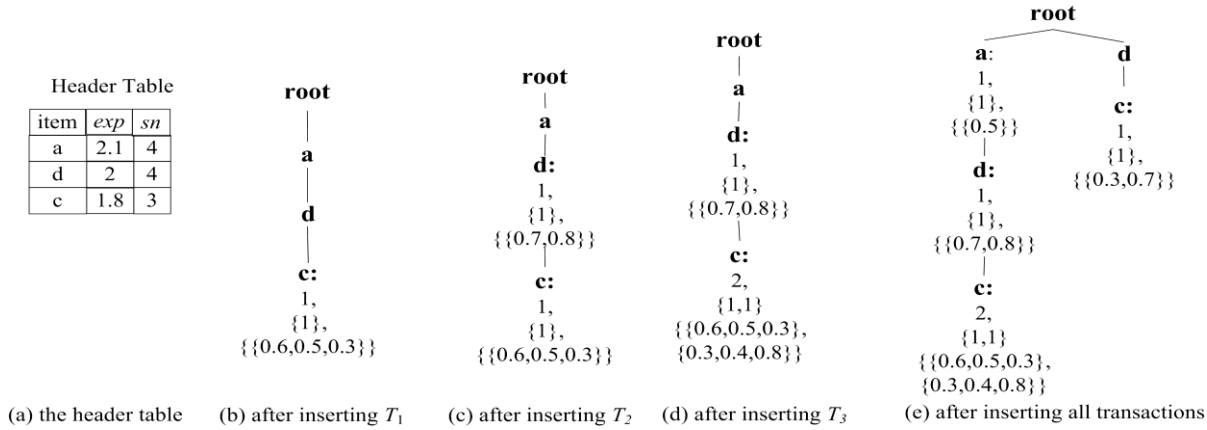

FIGURE 2 Construction of an IT-Tree

Figure 2a is a header table created in the first scan of dataset. Initially, the IT-Tree is created with a root R. When the transaction itemset T_1 is retrieved, the algorithm IT-Mine firstly deletes the item "b"; and then arranges the itemset in the order as the header table in Figure 2a; last, inserts the sorted itemset into the IT-tree. The resulting IT-Tree is shown in Figure 2b. On tail-node "c", "1" represents the support number of this transaction itemset, "{1}" represents the *base probability*, "{0.6,0.5,0.3}"

represents the probability values of items "a", "d" and "c" respectively.

Now insert the transaction itemset T_2 into the IT-Tree. Since the path "root-a-d" can be shared, the algorithm IT-Mine changes the node "d" to a tail-node for the transaction itemsets T_2. The resulting IT-Tree is shown in Figure 2c.

Afterwards, insert the transaction itemsets T_3 into the IT-Tree. Since the path "root-a-d-c" can be shared, only the probability information of this itemsets needs to be stored into tail node "c". The resulting IT-Tree is shown in Figure 2d. On the tail node "c", "{1,1}" represents the base probability values of two transaction itemsets, "{{0.6,0.5,0.3},{0.3,0.4,0.8}}" represents the probability values of items "a", "d" and "c" in two transaction itemsets respectively.

Figure 2e is the result after adding all transaction itemsets in Table 1 are added to the tree; this is the first IT-Tree, and we also call it the *global* IT-Tree. Since the conditional *base-itemset* of the first IT-Tree is null, the base probability of any tail node on the first IT-Tree is set to 1.

4.3 MINING FREQUENT ITEMSETS FROM THE TREE

Start processing from the last item (denoted as *Z*) in the header table (denoted as *HT*):

Step 1. Add item *Z* to the current *base-itemset* (which is initialized as null). Each new *base-itemset* is a frequent itemset.

Step 2. Let *Z.links* contain *k* nodes whose item name is *Z*; we denote these *k* nodes as $N_1,N_2,\ldots,N_k$ respectively; because item *Z* is in the last of the header table, all these *k* nodes are *tail nodes*, i.e., each of these nodes contains *probability information* (*S*, list of *BP*, list of *ItemsP*).

Substep 2.1. Since each one of these *k* nodes contains the probability of each item, create a sub header table through scanning these *k* branches whose paths are from these *k* nodes to the root.

Substep 2.2. Go to Step 3 if the sub header table is null.

Substep 2.3. Create a sub IT-tree for the current *base-itemset* {*Z*} according to the sub header table and these *k* branches. The probability values of items in the current *base-itemset* are stored to the corresponding tail-nodes.

Substep 2.4. Perform a recursive mining process on this sub IT-Tree.

Step 3. Remove the item *Z* from the *base-itemset*.

Step 4. For each of the *k* nodes (which we denote as N_i, $1\le i\le k$), modify its *tail-information*:

Substep 4.1. Delete item *Z*'s probability from list of *BP* of these *k* nodes.

Substep 4.2. Move the *probability information* (*S*, list of *BP*, list of *ItemsP*) on each node to the parent of each node.

Step 5. Process the next item in the header table *HT* using the same method.

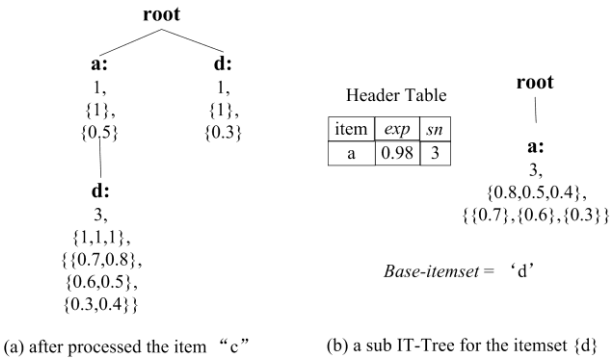

FIGURE 3 Mining the frequent itemsets

The following is the detailed explanation of the mining process illustrated in Figure 2 and Figure 3.

In Figure 2a, item "c" is the last item in the header table. Firstly, add item "c" to the *base-itemset*, and get a frequent itemset {c}; then create a header table for the current *base-itemset* by scanning the branches "root-a-d-c" and "root-d-c". For branch "root-a-d-c", under the condition of the current *base-itemset* {c}, the probability values of items "a" and "d" are calculated as 0.42 (=0.3*0.6+0.8*0.3) and 0.47 (=0.3*0.5+0.8*0.4); for branch "root-d-c", under the condition of the current *base-itemset* {c}, the probability value of item "d" is calculated as 0.21 (=0.7*0.3). The expected support numbers of items "a" and "d", 0.42 and 0.68 (=0.47+0.21), are less than the user specified *minimum expected support number* 0.8. So remove item "c" from the base-itemset, and remove the probability of each node "c" from *ItemsP* of each node, then pass the modified probability information to the parent node of this node. The resulting IT-Tree is shown in Figure 3a.

Afterwards, begin processing the item "d" in the header table in Figure 2a.

Add item "d" to the current *base-itemset*, we get a frequent itemset {d}; then create a header table for the current *base-itemset* {d} by scanning the branch "root-a-d" in Figure 3a; as the result, under the condition of the current *base-itemset* {d}, the expected support number of item "a" is calculated as 0.98 (= 0.5 * 0.6 + 0.4 * 0.3 + 0.8 * 0.7). Since this expected support number is not less than *minimum expected support number* 0.8, create a conditional sub IT-Tree and a sub header table for the current *base-itemset* {d}, as shown in Figure 3b. On tail-node "a" of Figure 3b, "{0.8,0.5,0.4}" represents the base probability values of 3 transaction itemsets containing the itemset {da}, "{{0.7},{0.6},{0.3}}" represents the probability value of the item "a" in 3 transaction itemsets respectively.

Now, the item "a" in header table in Figure 3b is processed.

Add item "a" to the current *base-itemset* {d}, and get a frequent itemset {da}. After the sub IT-tree in Figure 3b is processed, return to process previous tree in Figure 3a.

Go on processing the next item "a" of the header table in Figure 2a.

After finish processing item "a", we get a new frequent itemset {a}.

Lastly, we find 4 frequent itemsets from the dataset in Table 1: {c}, {d}, {da} and {a}.

5 Experimental results

In this section, we compare the performance of the proposed algorithm IT-Mine, the level-wise algorithm MBP and the pattern-growth algorithm UF-Growth using five datasets.

TABLE 2 Dataset characteristics

Dataset	|D|	|I|	ML	DS (%)	Type
retail	88162	16470	10.3	0.06	sparse
T20I6D100K	100000	980	20	2.03	sparse
mushroom	8124	119	23	19.33%	dense
connect	67557	129	43	33.33	dense
T20I6D200K	200000	980	20	2.03	sparse

Table 2 shows the characteristics of 5 datasets used in our experiments. "|D|" represents the number of transactions; "|I|" represents the number of distinct items; "ML" represents the mean length of all transaction itemsets; "DS" represents the degree of sparse or dense. The datasets *retail*, *mushroom* and *connect* are real-world and obtained from FIMI Repository [21]. The datasets *T20I6D100K* and *T20I6D200K* came from the IBM Data Generator [13**]**. Because the original datasets do not provide probability values for each item, to use these dataset as uncertain transaction dataset, we assign a randomly generated existential probability from range (0, 1] to each item of each transaction itemset. The runnable programs and testing datasets used in our experiments can be downloaded from the following address: http://code.google.com/p/it-tree/downloads/list.

The configuration of the testing platform is as follows: Windows 7 operating system, 3G memory, Intel(R) Core(TM) i5-2300 CPU @ 2.80 GHz; Java heap size is 1024M.

The minimum expected support number is set from 130 down to 40 with the decreasing of 10 on *retail*, from 160 down to 70 with the decreasing of 10 on *T20I6D100K*, from 550 down to 100 with the decreasing of 50 on *mushroom*, and is set from 9000 down to 7200 with the decreasing of 200 on *connect*. The more the number of frequent itemsets is, the smaller the minimum expected support number is set. Under the upper bound of the minimum expected number on our experiments, there are at least frequent 2-itemsets on those datasets. As shown in Figures 4-7, they show the distribution of frequent itemsets (FIs) under different minimum expected support number.

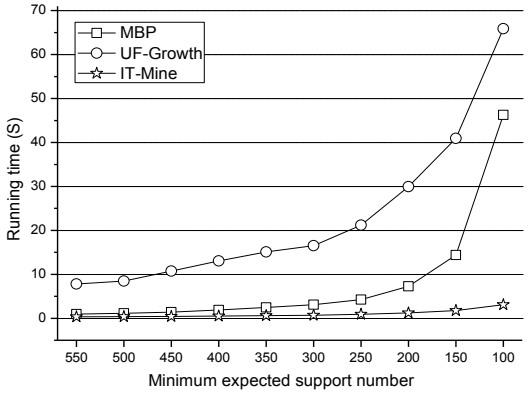

FIGURE 10 Ru3nning time on mushroom

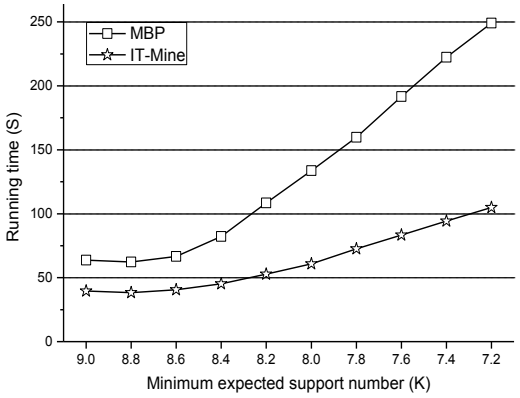

FIGURE 11 Running time on connect

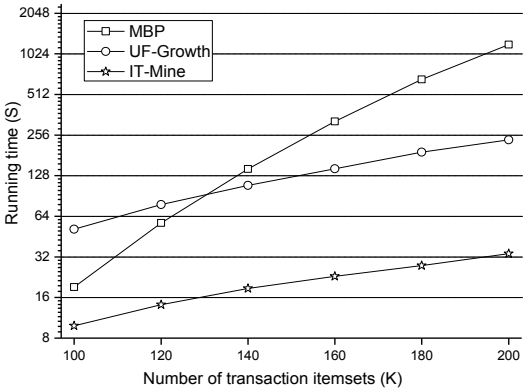

FIGURE 12 Scalability for the algorithms on the sparse dataset

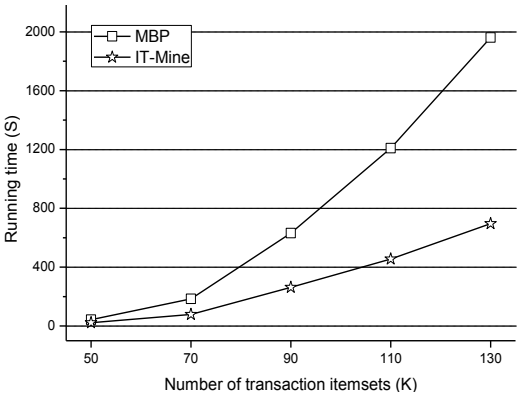

FIGURE 13 Scalability for the algorithms on the dense dataset

Figures 8-11 show the running time of 3 algorithms on four testing datasets under different minimum expected support number. On the dense dataset *connect*, UF-Growth is out of memory although the minimum expected support number is set 9000 because the dataset connect is very dense and the length of each transaction itemset is 43. The time performance of UF-Growth is low because UF-Growth generates too many tree nodes and requires too much time to process these tree nodes. The number of candidate itemsets generated by MBP increases with the decreasing of the minimum expected support number, as shown in Table 3. For example, the number of candidate itemsets is up to 2756787 from 143524 when the minimum expected support number is down to 40 from 130 on *retail*, thus the running time of MBP increases quickly with the decreasing of the minimum expected support number. Figures 8-11 shows that IT-Mine has a high time performance on those four dataset under different minimum expected support number.

In the following experiments, we evaluate the scalability of IT-Mine, UF-Growth and MBP on sparse datasets using the synthetic sparse dataset T20I6D200K; we vary the size of the dense dataset *connect* to evaluate the scalability of IT-Mine, UF-Growth and MBP on dense

datasets; The minimum expected support number is set 120 and 8000 on the sparse dataset and dense dataset respectively.

MBP requires generating candidates and identifying frequent itemsets from the candidates by scanning the dataset, thus its time performance is dependent on the numbers of candidates, the size of dataset and the length of transaction itemsets. As shown in Figure 12 and Figure 13, the time performance of MBP slows down drastically with the increasing of number of transaction itemsets. Both IT-Mine and UF-Growth have a stable time performance on the sparse dataset. On the dense dataset, because the length of each transaction itemset is long and the dataset is very dense, UF-Growth is out of memory in our experiment of dense dataset and the time performance of MBP also slows down with the increasing of the size of dataset. Figure 12 and Figure 13 show that the strong scalability of IT-Mine is obvious.

6 Conclusion and discussion

In this paper, we propose a novel tree structure, named IT-Tree, to represent transaction itemsets of an uncertain transaction dataset. An important feature of IT-Tree is that it maintains probability information of each transaction itemset into a tail-node of the transaction itemset. This way the IT-Tree is as compact as the original FP-Tree, while it does not lose information with respect to the distinct probability values for transaction itemsets. We also give an algorithm named IT-Mine to mine frequent itemsets from IT-Tree without additional scans of dataset.

Experiments were performed on both real sparse and dense dataset, and IT-Mine outperforms the algorithm MBP and UF-Growth in terms of running time; the performance of IT-Mine is also quite stable with the changing of the minimum expected support number.

There are two models in mining frequent itemsets from uncertain transaction dataset: one is based on the *expected support number* of an itemset; the other is based on *occurring probability* of an itemset. IT-Mine is developed on *expected support number*, but it can also be applied to the latter model, because after getting probability information from the tree, the data structure itself is irrelevant with the calculation of the *expected support number* or the *occurring probability* of an itemset.

Although IT-Mine has achieved better performance on testing dataset, construction of global IT-Tree and conditional IT-Trees consumes much time. We hope to improve the speed of IT-Tree construction in future work.

Abstract

To effectively reduce the amount of 3D point cloud data, whose shape is symmetrical or spherical, this paper proposes an efficient simplification algorithm based on ray theory. Meanwhile, a boundary retention method based on the distribution uniformity of neighbouring data points is used to keep the model complete. Avoiding time-consuming recursion and curvature estimation, the proposed method is much efficient and achieves good simplification results.

Keywords: 3D Point Cloud, Data Simplification, Ray Generation, Boundary Retention

1 Introduction

In recent years, with the decrease in cost and the increased precision of 3D scanners, 3D point clouds have become an important data representation form in graphics, reverse engineering, and industrial fields [1]. However, the huge of original 3D point cloud data causes great difficulties in 3D reconstruction. As a result, denoising and simplification of the 3D point cloud are important pre-processing steps [2]. Algorithms for simplifying 3D point cloud data include simplification based on clustering [3-5] and simplification based on curvature [6-8], amongst others. Although these methods can reduce the size of the point cloud, retain characteristics of the point cloud model, and increase the reconstruction efficiency of the model to some extent, most of them require recursive calculations and curvature estimation. Thus, these algorithms are quite time-consuming, especially for models with enormous point cloud data.

This paper aims at reducing 3D point cloud data whose shape is symmetrical or spherical, such as head, fruit, mechanical devices et al. In this paper, in order to simplify 3D point cloud data, we assume, based on the ray principle, that the centre of a 3D point cloud model generates several rays, and that data locates at a certain distance from the rays will be reduced. Meanwhile, a boundary retention method based on distribution uniformity of neighbouring data points is used to retain the boundaries of the model [9, 10], thereby guaranteeing the completeness of the data after simplification.

To conduct a rapid local search of data points, a kd-tree is constructed to establish the topological relations among the point cloud data. The organized point data structure of the kd-tree in a k-dimensional Euclidean space is a special binary tree. There are many studies on search of k nearest neighbours in a kd-tree, please refer to [11].

2 Foundation of the proposed algorithm

2.1 RAY PRINCIPLE

The ray principle is simple and easy to understand. First, suppose that the central point of the point cloud data generates rays evenly in all directions, as shown in Figure 1(a), with the rays filling the entire 3D space. Regarding the point cloud model (as shown in Figure 1(b, c)) in this space, if the distance from a certain point in the model to the nearest ray is smaller than a given distance, this point will be simplified. The denser the rays are, the greater the distance is, and the more data points in the 3D point cloud model can be reduced. Therefore, different degrees of simplification results can be achieved by controlling the number of rays and other parameters.

FIGURE 1 Generation principle of rays

2.2 RAY GENERATION

Since the ray principle is the foundation of this paper, the simplification result of the point cloud model is directly related to the way that the rays are generated. Basically, two points make up one line, the centre of the 3D point cloud model is set as one point for all rays. Thus, the

[*] ***Corresponding author*** e-mail *meili_w@nwsuaf.edu.cn*

coordinates of the other points must be generated according to a specific rule, to form all rays. For convenience of generating coordinate points, a minimum cube V_m that encircles the point cloud model is first generated. Suppose that the length of this cube is L, and the maximum and minimum values of the scattered point cloud in the directions of the X-, Y- and Z-axes are $X_{\max}$, $Y_{\max}$, $Z_{\max}$, $X_{\min}$, $Y_{\min}$, and $Z_{\min}$, respectively. Then, the length of the cube is calculated as

$$L = Max((X_{\max} - X_{\min}), (Y_{\max} - Y_{\min}), (Z_{\max} - Z_{\min})). \quad (1)$$

A cube that entirely encircles the point cloud model is created by setting L as the length and $(X_{\min}, Y_{\min}, Z_{\min})$ as the vertex. Then, the required points are generated on the six sides of the cube. By taking a plane parallel with the *XOY* plane as an example as shown in Figure 2, suppose that the two sides of this plane parallel with the X- and Y-axes are $L1$ and $L2$, respectively, and the end vertexes of the two sides are $P_1(x_1, y_1, z_1)$, $P_2(x_2, y_2, z_2)$, P_2 and $P_3(x_3, y_3, z_3)$, respectively. The coordinates of the generated point $P_i(x_i, y_i, z_i)$ are calculated as

$$x_i = (i/n) \times (x_1 - x_2) + x_2 \quad (i = 0,1,2...,n-1,n) \quad (2)$$

$$y_i = (i/n) \times (y_3 - y_2) + y_2 \quad (i = 0,1,2...,n-1,n) \quad (3)$$

$$z_i = z_1 = z_2 = z_3 \quad (i = 0,1,2...,n-1,n) \quad (4)$$

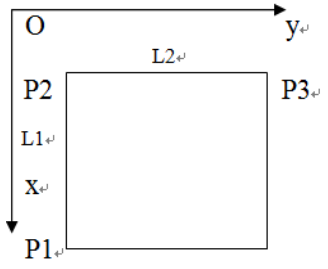

FIGURE 2 Schematic diagram of x-y plane of cube V_m

The number of points generated on each plane is $(n-1)^2$, and $(n+1)^2+4$ rays can be formed. In this way, the number of rays can be controlled by adjusting parameter n.

2.3 DETERMININATION OF THE DATA POINTS FOR SIMPLIFICATION

To increase efficiency, the equation of the line on which the ray is located is not calculated, instead, the distance from the point to the line is calculated using the relation between the vectors. Suppose that the direction vector of line L is $s = (n, m, q)$, M is a point on the line and p is a point beyond the line. Thus, the distance from p to L is $d = \frac{|\overrightarrow{MP} \times s|}{s}$. If d is less than the given distance dis, then p should be reduced; otherwise p will be retained. dis is used as the judgment distance to control the degree of simplification. In this paper, locations far away from the central point, lines will be sparse, and thus the simplification degree will be low. Therefore, dis should vary with a change in the distance from the data point to the central point. The greater the distance, the greater the value of dis should be. Suppose that the central point is Mid and the data point is p_i; dis_i is used as the judgment distance when carrying out the simplification operation for each data point, dis_i is computed by Equation (5), where x is an input, used to control the value of dis_i and the point cloud quantity is Max. Let

$$dis_i = x \times Dis\tan ce(Mid, p_i)^2, \quad (i = 0,1,2...Max), \quad (5)$$

where $Dis\tan ce(Mid, p_i)$ denotes the distance from Mid to p_i. The simplification degree can be controlled by x.

3 Boundary retention

It is important to retain the boundary of the model during the data simplification procedure in that the boundary information is vital to keep the final reconstructed model complete. Thus, keeping the boundary points is also discussed in this paper.

FIGURE 3 Result without boundary retaining treatment

FIGURE 4 Result with boundary retaining treatment

Figure 3 and Figure 4 illustrate the data simplification results with and without applying the boundary retention method. It can be seen that using the boundary retention method, the boundary is complete, thereby improving the effects of data simplification effectively. There are proposed several methods for retaining the boundary points of a model. For example, when determining whether a point is a boundary point [12], several neighbouring points must be searched firstly using the topological relations among the point cloud, and then a least squares plane is constructed in the space based on the neighbouring points. Whether a point is a boundary point is determined by the distribution uniformity of the neighbouring point projection on the least squares plane. Meanwhile, the boundary retention degree can be controlled through a proportionality coefficient e. In this method, when calculating the distribution uniformity of the neighbouring point projection, either the standard deviation of the included angle must be calculated or the coordinate values must be compared. Besides, a boundary point judgment must be made for each data point.

We proposed a method to improve the method for determining boundary points by a way of comparing point cloud coordinate values. In this method, boundary point determination is not carried out for every data point, if a certain point is a non-boundary point, then several neighbouring points of this point are probably not boundary points either. We define that Num denotes the number of point clouds in which neighbouring points are treated as non-boundary points without any judgment, if a certain point is detected as a non-boundary point. This value increases with an increase in the data size of the 3D point cloud model. Through combined control of the proportionality coefficient e and Num, this method has little influence on the boundary retention effect. Figure 5 and Figure 6 show the results of making a boundary judgment, respectively, for each point or only for certain points using the proposed method. The value of the proportionality coefficient e in Figure 5 and Figure 6 is 0.9 and 0.85, respectively, while the threshold value Num is set to 1. It can be seen that there are no obvious differences in the results. However, execution of the former method takes 3.75 s, while the latter only requires 2.70 s. Therefore, the proposed method effectively improves the performance.

FIGURE 5 Result of making a boundary judgment for each point

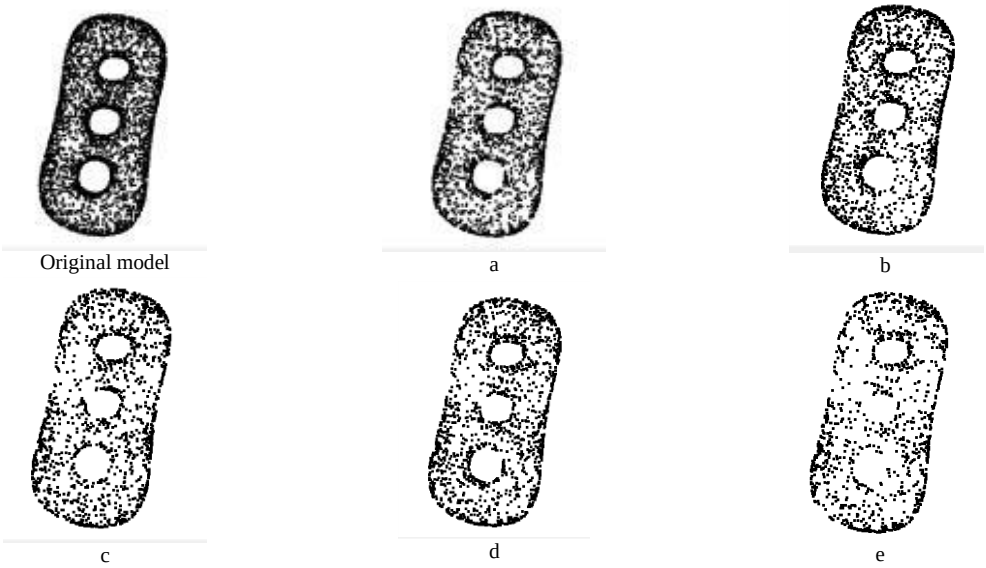
FIGURE 6 Result of making a boundary judgment for some points

4 Simplification results and analysis

The experiments were conducted on Intel CORE i5-3210M, 2.50 Hz processor and 4.00 GB memory. Table 1 gives the test data for simplification under different parameters, while Figure 7 shows the corresponding simplification results, The proportionality coefficient e is only used to control the boundary retention degree of the point cloud model, and therefore its value remains unchanged in general situations, e is set to be 0.85.

TABLE 1 Test results under different parameters

Test number	Model	Input points	d	x	Output points	Execution time (s)
test1	Test model	4000	10	0.11	2592	0.96
test2			15		2036	1.72
test3			20		1514	2.25
test4			10	0.23	1729	1.19
test5				0.35	1125	1.21



Original model a b

c d e

FIGURE 7 Simplification results

According to Table 1 and Figure 7(a, b and c), since the simplification degree is controlled by the number of generated rays, a more number of rays requires a longer execution time. According to Table 1 and Figure 7(a, d and e), the simplification degree is controlled by the value of x, a larger x varies the simplification degree, the execution time has not change much. However, a larger x will lead to holes in the model. Therefore, under the premise that the simplification effect is not affected, threshold x can be increased as much as possible to improve data simplification efficiency.

Table 2 presents the test results for a model using the proposed algorithm and the traditional data simplification algorithm, which involves curvature estimation and recursion. By adjusting the relevant parameters, the number of output points is approximately achieved. Figure 8 shows the simplification effects of Model1 of Table 2, respectively.

TABLE 2 Comparison of the proposed algorithm and traditional curvature estimation algorithm

Model	**Input points**	**Output points**		**Execution time(s)**	
		The traditional algorithm	The proposed algorithm	The traditional algorithm	The proposed algorithm
Model1	4102	1162	1196	2.02	0.94

a. Original model b. Effect of simplification involving curvature estimation and recursion c. Simplification effect using proposed algorithm

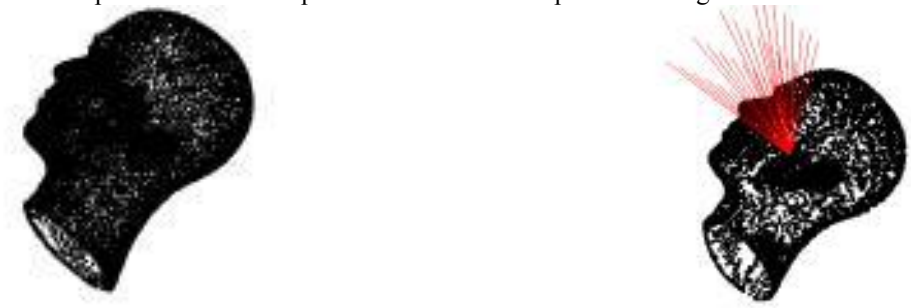
FIGURE 8 Comparison of simplification effects for Model1

It can be seen from Table 2 and Figure 8 that the proposed algorithm is more efficient than the traditional curvature estimation algorithm, while good simplification effects are guaranteed.

The proposed algorithm is based on the ray principle, and thus is more suitable for simplification under a ball model or point cloud model with symmetrical structure. Figure 9 and Figure 10 depict a schematic diagram of the simplification effects as well as some of the rays when applying the proposed algorithm to a ball model and a symmetrical model.

As shown in Figure 9 and Figure 10, according to the definition of the central point in the ray generation method used in this paper, all central points used to generate rays are approximately located in the central position of the entire model when data simplification is carried out for Model 1 of Figure 9 or Model 2 of Figure 10. In this situation, results of data simplification are more even. Regarding approximate ball models, the

distance from the central point to each surface of the model is almost the same, and thus every part of the model can be reduced by a similar degree. Besides, the central point will not be too close to a certain surface of the model when simplification is completed for ball models. According to the ray principle, rays are dense at places near the central point. If the central point is too close to a certain surface of the model, this part can be reduced more easily than other parts when the simplification degree is increased.



a. Original model b. Schematic diagram of simplification effects and some rays

FIGURE 9 Model 1(Ball model)

a. Original model b. Schematic diagram of simplification effects and some rays

FIGURE 10 Model 2(Symmetrical model)

5 Conclusion

In this paper, we proposed a novel and efficient simplification algorithm for 3D point cloud data, whose shape is symmetrical. The experimental results have shown that within a certain degree of simplification, this algorithm achieves good simplification effects and high efficiency. The proposed algorithm is especially suited to ball and symmetrical models. To increase the adaptability to solve the problem whereby an unreasonable central point of the model negatively affects the simplification effect, the central point of the model will be set as a flexible point in the future research. In this way, the position of the central point can be adjusted according to the actual simplification model, thereby improving the simplification results and the efficiency.

Abstract

To resolve the problem that virtual machine deployment reservation scheme waste a lot of resources and single-objective deployment algorithm is not comprehensive, a virtual machine resource allocation algorithm based on virtual machines group multi-objective genetic algorithm is proposed. The algorithm is divided into group coding and resources coding. Resources coding integrated coding according to the history resource need of virtual machines to physical machine and integrate number of physical machine and resource need of physical machine occupied by virtual machine through improved crossover and mutation operations. The experimental results show that the algorithm is effective to reduce the number of physical machine and resource utilization of physical machine, saving energy as much as possible.

Keywords: Cloud computing, Resource allocation, Virtualization, Energy-saving, Genetic algorithms

1 Introduction

Cloud computing is a type of new computing model, providing all kinds of serviced through Internet. Users can gain access to the cloud service anytime, anywhere and on any device. Virtualization technology plays a critical role in management of cloud resource and dynamic configuration, for all kinds of underlying hardware resources can be encapsulated by virtualization technology and provides services to users with virtual machines as the basic resource unit [1]. However, since cloud computing platform includes highly dynamic and heterogeneous resources, virtual machines has to adapt to the dynamic cloud computing environment [2]. The purpose of virtual machines deployment strategy is realizing ideal result by changing layout and placement of overall virtual machines to optimize the objective in meeting constraint condition. The problem of virtual machines placement proved to be *NP* problem. Thus, it is a research hotspot in current cloud computing filed how to conduct virtual machines placement effectively.

Currently, single-objective resource allocation and deployment method are usually adopted in the field of virtualized server technology application. With the goal of maximizing utility, the literature [3] utilizes *NUM* model in computer network. One or more physical machines resources, like bandwidth of network link, distributes one or more job by virtualization technology, reaching higher level of allocation of computing resources of physical machines and optimizing it by algorithm. With the goal of energy-saving, the literature [4] dynamically deploys virtual machines application by energy-aware heuristic algorithm. The literature [5] put forward an improved preferential cooperation descending method to solve the problem of node bin packing. The method merely involves node integration during peak load situation, without consideration of constraint that the goods may be incompatible with the box. The literature [6] suggests an adaptable management frame for virtual machines placement, and studies on the solution of genetic algorithm to the overall placement of virtual machines, effectively reduce the number of physical machines and migration times, but not considering the integration of physical machines resources by virtual machines in the solving process. Nowadays, the optimal method of most virtual machines placement is transforming multi-objective optimization problem to several single-objective optimization problems to be solved in stages. It rarely happens that multi-objective is optimized at the same time. In most time, only partial optimal solution rather than global optimal solution is gained.

For the issue of server integration and resource allocation in cloud computing, a virtual machines resource allocation algorithm based on virtual machines multi-objective genetic algorithm is proposed. With the aim of reduce the number of physical machines and resource allocation, a best solution is searched by genetic algorithm to saving energy as much as possible.

2 Resource allocation algorithm in cloud computing

The definition of bin packing problem [7] is that a set S of M in size and a set P of N in size given, how all

* ***Corresponding author*** e-mail: 1292815809@qq.com

elements of *S* are packed in elements of *P* with least elements of *P* used. *BPP* problem, a difficult *NP* problem, cannot be done by a known optimal algorithm in polynomial time. The problem of virtual machines deployment is actually bin packing problem. In cloud computing, how to reasonably deploy virtual machines to relevant nodes shall be considered, realizing optimal usage of resources while meeting service objectives of different applications. The virtual machines placement may be regarded as vector bin packing problem. The goods being packed are the virtual machine under operation, and the resources of virtual machine are the changeable size of goods. The box is the physical node, and the capacity of the box is the usage threshold of node resource. The number of types of resources is the number of dimensions of vector bin packing problem. Assuming that the number of physical nodes is *M* and the number of virtual machines is *N*, the solution space from the virtual machines to the physical nodes is M^N . It is a *NP* problem similar with bin packing problem that requires an approximate optimal solution.

2.1 DESCRIPTION OF ISSUES IN MULTI-OBJECTIVE VIRTUAL MACHINES DEPLOYMENT ALGORITHM

The resource asked by users to the cloud platform is equal to s virtual machine requiring specific resource, and the applications package of each user operates on their own virtual machines. It is an academic research hotspot how to save energy and utilize cloud computing resource as much as possible to deploy multi-objective virtual machines. Deploying multi-objective virtual machine problem is a multiple combination optimization problem, as well as multi-objective optimization problem. The available resource of each physical machine is multi-dimensional vector, with each dimension as one of all resources of physical machines, and the resource needed by each physical machine is also multi-dimensional vector. The objective is to allocate several virtual machines to several physical machines, maximizing each resource utilization rate of physical machines and minimizing the number of virtual machine immigration. The multi-objective deployment problem is described as follows:

Make N_{PM} as the physical machine set in cloud computing, N_{VM} as virtual machine set in cloud computing, *N* as the total number of virtual machines, N_R as the available allocated resources set in cloud computing and *K* as the total number of available allocated resources.

The objective: $max\sum_{m=1}^{M}\sum_{k=1}^{K}U_{m,k}$ and $min\sum_{m=1}^{M}P_m$.

$\forall n \in N_{VM}, \forall m \in N_{PM}$, among them, $U_{m,k}$ is usage rate of the *K* type of resource by physical machine *m*, P_m is the number of nodes of physical machines.

Constraint:

$$P_m \in \{0,1\} . \quad (1)$$

If $P_m = 1$, it means using new physical machine.

$$U_{m,k} < C_{m,k}, \quad (2)$$

$$\sum_n U_{n,k}^{\ m} < C_{m,k} . \quad (3)$$

Among them, $C_{m,k}$ means the threshold value of the *K* type of resource of *m* physical machine. $U_{n,k}^{\ m}$ is the usage rate of the *K* type of resource by the *n* virtual machine under *m* physical machine. The operation of each type of resource of each physical machine shall be less than the threshold value of each type of resource during the virtual machine deployment process. When there are several virtual machines under deployment in *m* physical machine, the total usage rate of resources of virtual machine under physical machine shall be less than the threshold value of each type of resource.

2.2 DESIGN AND REALIZATION OF MULTI-OBJECTIVE VIRTUAL MACHINES DEPLOYMENT ALGORITHM

For the huge cloud computing centre, combinational explosion may occur in combinatorial optimization. Genetic algorithm is one of the methods for solving combination problem now, since it can concurrently handle with all objectives and avoid priority ordering among objectives. Therefore, genetic algorithm is very suitable for solving multi-objective optimal issues [8]. A virtual machine resource allocation algorithm based on virtual machines multi-objective genetic algorithm is proposed, on the basis of multi-objective virtual machines deployment problem in cloud computing centre.

2.2.1 Coding

In the virtual machines deployment problem, there are three types of genetic coding methods: (1) the representation based on box; (2) the representation based on goods; (3) the representation based on group. Since the objective function of bin packaging problem relies on the goods group, the former two coding methods face single goods, with shortcoming of unclear grouping information. The shortcoming of the third coding method is relying on goods group, neglecting the difference of utilization of physical machine resources by each virtual machine in the crossover and mutation process. In the paper, combining with the coding method based on group

and goods, dynamic allocation genetic algorithm of cloud computing resources is proposed.

The coding based on goods in the paper mainly adopts the coding based on the resource need of virtual machine to the physical machine. The resource need of virtual machine to the physical machine taking CPU, disc and network as example, by *N* number of samplings of *i* virtual machine in a while *T*, calculates the number of operations of CPU, disc and network according to the sampling points. Then the number of operations is coded, and the number of operations of CPU, disc and I/O are showed as formulas (4), (5), and (6). In order to understand the change of demand of virtual machine for resources, the author of the paper adopts the energy efficiency models in the literature [9] for data sampling.

$$L_c^i(T)=\sum_{t=1}^{N}\left[C_f^i(t)\times C_u^i(t)\times C_c^i\times C_{fn}\right]. \quad (4)$$

Among them, $C_f^i(t)$ is the CPU frequency of *i* virtual machine at *t* time; $C_u^i(t)$ is the usage rate of CPU of *i* virtual machine at *t* time; C_c^i is the number of CPU cores of *i* virtual machine; C_{fn} is the number of calculation of floating point in each period.

$$L_d^i(T)=\sum_{t=1}^{N}\left[D_r^i(t)+D_w^i(t)\right]. \quad (5)$$

Among them, $D_r^i(t)$ is the data amount read from disc of *i* virtual machine per second at *t* time; and $D_w^i(t)$ *i*s the data amount written to disc of *i* virtual machine per second at *t* time.

$$L_n^i(T)=\frac{1}{2}\sum_{t=1}^{N}\left[N_r^i(t)+N_w^i(t)\right]. \quad (6)$$

Among them, $N_r^i(t)$ is the data amount received by network card of *i* virtual machine per second at *t* time; and $N_w^i(t)$ is the data amount sent by network card of *i* virtual machine per second at *t* time.

Then calculate the probability of the calculation amount of three types of resources needed by each virtual machine in the calculation amount of physical machine recourses and conduct normalization processing. The formula of probability of the calculation amount is as the following formula (7).

$$P_i=\frac{\mu_i}{\sum_{i=1}^{Z}\mu_i}. \quad (7)$$

Among them, μ_i is the calculation amount of CPU, disc and I/O of *i* virtual machine; and *Z* is the number of virtual machines in physical machines of *i* virtual machine. P_i may be the CPU calculation probability of CPU, disc and I/O of *i* virtual machine.

Then normalization processing is conducted according to the ratio of probability *H* of in the entire set of all types of resources in current physical machine. The value is in the range of [0, 10]. and the probability distribution is shown in figure 1.

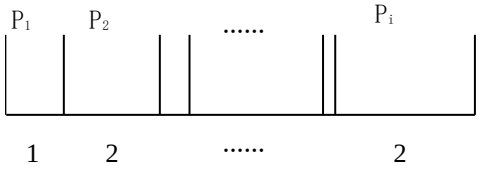

FIGURE 1 Probability distribution graph

Make c_i , m_i , n_i represent the coding of the resource need by CPU, disc and network, and make the proportionality distribution of all types of resources of *i* virtual machine after normalization processing as the resource coding of *i* virtual machine.

Constraint: $c_i\in[0-9], c_i\in N^*$, $m_i\in[0-9], m_i\in N^*$, $n_i\in[0-9], n_i\in N^*$.

Make T_c as the threshold value of CPU resource of physical machine, T_m as the threshold value of disc resource of physical machine and $T_{I/O}$ as threshold value of CPU resource of physical machine. In order to better illustrate the algorithm rose in the paper, the values of T_c, T_m and $T_{I/O}$ in the genetic operation process is 8. The threshold less than 10 is for reserving part of resource space for immigration of virtual machines.

The coding method is shown as figure 2. It mainly takes group as chromosome that has uneven length for the inconsistent number of genes in chromosome. There are three types of deployment of 9 virtual machines: the length of EBA and FCQ are the same but the types of deployment are different; both the length of chromosome of EBA and FCQ as well as the types of deployment are different.

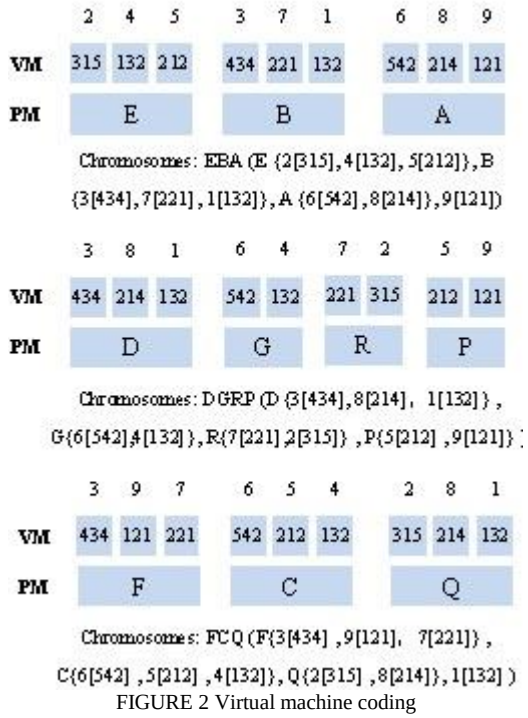

FIGURE 2 Virtual machine coding

2.2.2 Evaluation of fitness

Genetic algorithm evaluates the pros and cons of individuals according to fitness. Fitness function means the corresponding relevance between the whole subjects and their fitness. Evaluation of fitness conducts evaluation of each individual and prepare for the next genetic operation. Since the objective function adopts physical machines as less as possible to place virtual machines as more as possible, the fitness function is shown as the following formula (8), according to the objective function and constraint condition:

$$Fitness_j = \sum_{i=1}^{P_j} \sum_{k=1}^{K} U_{i,k}{}^{j} / P_j . \quad (8)$$

Among them, j means the number of father node, P_j as the total number of physical machines used by father node, and $U_{i,k}$ as the utilization rate of k type of resource of i virtual machine.

2.2.3 Crossover

The main function of the crossover process in genetic algorithm is letting the next generation inherit the excellent genes from the parents and have chance to produce more excellent generations. There are two parts of the crossover process: one is crossover process based on group coding aiming to minimize the number of physical machines, and the other one is crossover process based on resource coding aiming to maximizing the resource of physical machines.

Crossover process based on group coding is shown in figure 3 with steps as follows:

1. Randomly select two father nodes, cross part and cross dot.
2. Insert a selected virtual machine to father node to form new deployed physical machine setoff virtual machines.
3. Delete the repetitive virtual machines in the new physical machine set.

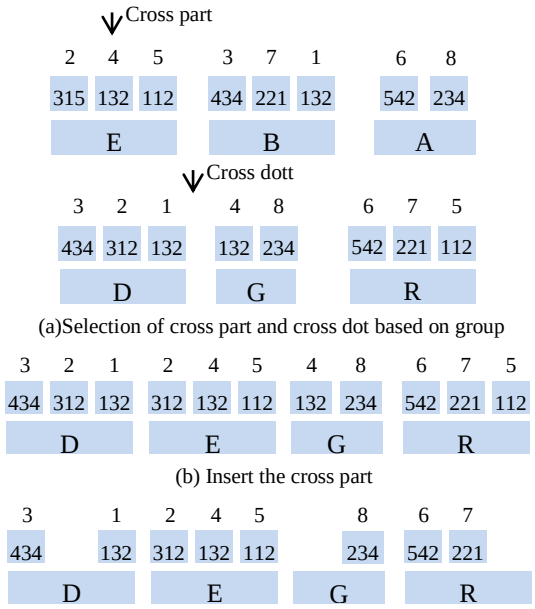

FIGURE 3 Coding cross process based on group

Based on the resource coding crossover process and group coding crossover process, the genetic operation of resource coding can fasten the convergence speed of the group coding genetic process, and integrate the resource of physical machine occupied by the virtual machines. In order to reserve the group crossover result, the resource coding crossover process will reserve the inserted virtual machine group of group coding, not conducting resource coding crossover to it.

Crossover process based on resource coding is shown in figure 4 with steps as follows:

1. Select the remaining virtual machine of the first father node and the second father node (excluding the cross part) of the group coding crossover result as the father nodes. Select the cross part and cross dots. Now the cross part is the virtual machine but not the virtual machine group.
2. Insert the selected virtual machine to virtual machine group.
3. Combine independent virtual machines and delete repetitive physical machine as well as physical machine without any virtual machine.
4. Combine the results of group coding crossover process and resource coding crossover process to get the crossover process result.

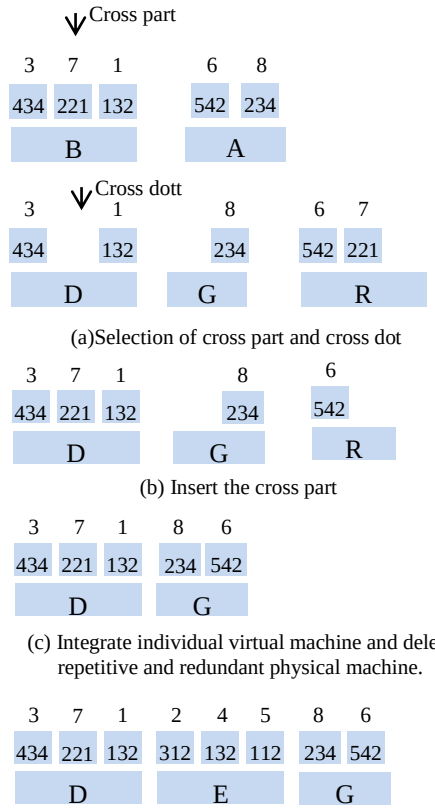

FIGURE 4 Cross process based on resource coding

3 Experimental analysis

In order to verify the proposed algorithm, the author conducts simulation experiment in CloudSim [10]. With the purpose of verifying the effectiveness and deployment scheme, we select the following two classical virtual machine deployment algorithm （Multi-object virtual machines resource allocation Algorithm, MOA） to compare with the multi-objective virtual machine resources distribution algorithm.

Best Fit Algorithm (BFA) means to select the physical machine that meets the resource need of virtual machine with least remaining resource during the virtual machine deployment process, making the physical machine least remaining resource. First Fit Algorithm (FFA) means to search physical machines in order during the virtual machine deployment process, letting virtual machine directly deployed in the physical machine that meets the resource need of virtual machine.

Experiment 1 Calculation of number of physical machines

Deploy 100 virtual machines in 50 physical machines using three types of algorithm independently, with the same nature of physical machines and virtual machine tasks excepting the deployment method and resource threshold value. Among them, the crossover proportionality and mutation proportionality of multi-objective virtual machine deployment algorithm is 0.7 and 0.5 respectively, and the genetic algebra is set as 10. There are load parameter and change of virtual machine resource need during the experiment, taking 10 minute as a time unit to record the change of number of physical machines in 10 time units by three types of algorithm. The experiment result is shown as figure 5:

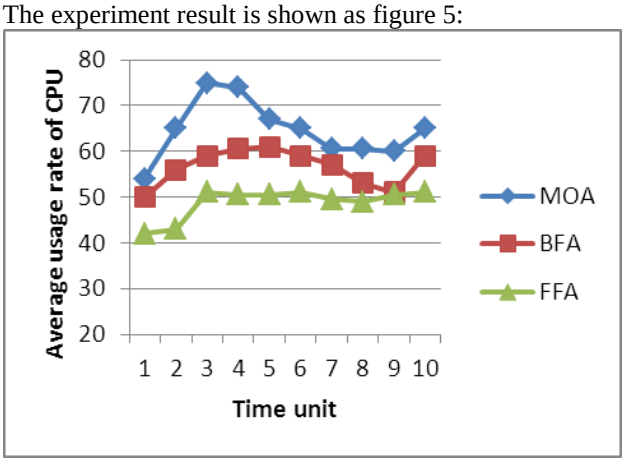

FIGURE 5 Comparisons of number of physical machines

The experiment shows that as time goes on, with the dynamic change of virtual machine's need of resource, the number of physical machines in MOA algorithm is less than that of BFA and FFA. It is because that in a dynamic process, MOA algorithm searches the least number of physical machines in generic operation that meets the constraint condition. It shows that MOA algorithm can effectively reduce the number of physical machines.

Experiment 2 Calculation of resource utilization rate

Calculate the average resource utilization rate of physical machines by three types of algorithm, taking 10 minute as a time unit to record the change of usage rate of CPU and inner storage of physical machines in 10 time units, and calculate the average resource utilization rate. The experiment results of average usage rate of CPU and inner storage by three types of algorithm are shown in figure 6 and 7.

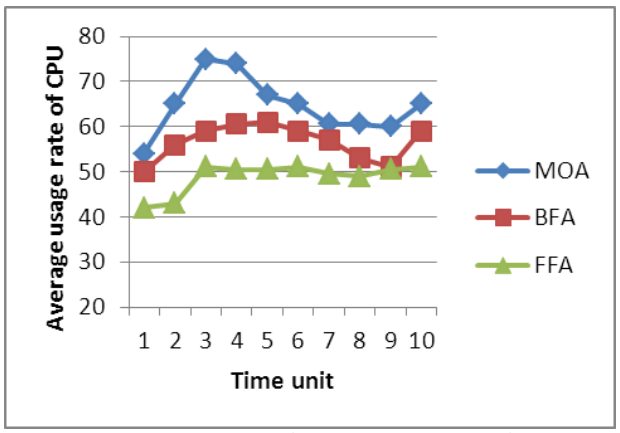

FIGURE 6 Comparisons of the average usage rate of CPU

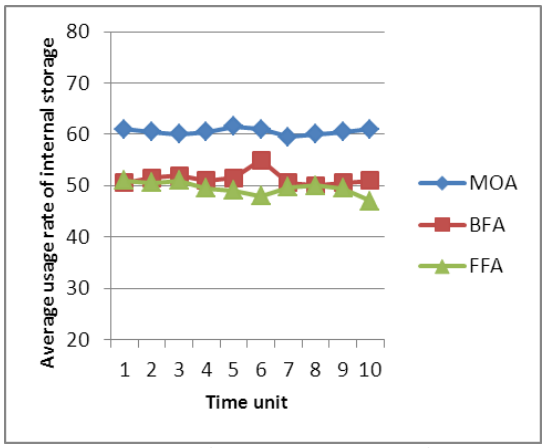

FIGURE 7 Comparisons of the average usage rate of internal storage

It shows from the compared experimental results that the average usage rate of CPU and internal storage of physical machines deployed by MOA algorithm is evidently higher than that of BFA and FFA algorithm. It is because MOA try to improve the resource usage rate as much as possible by using genetic algorithm to adjust virtual machine group during the deployment process, while BFA algorithm try to deploy physical machines as less as possible but not considering improving the resource usage rate, and there are randomness in FFA algorithm that does not consider the resource usage rate. It shows that MOA algorithm can improve the resource usage rate and save energy to some extent.

4 Conclusion

In the paper, after analysing the research situation of virtual machine deployment scheme in cloud computing, the author put forward improved genetic algorithm, conduct group coding and resource need coding of virtual machine, and improve the crossover and mutation operation to resolve the problem of energy waste in cloud computing. Under experimental condition, it shows that the algorithm can not only reduce the number of physical machines but also improve the resource utilization rate. In further research, the issue whether the performances among virtual machines are related will be introduced.

Multi circle detection by using evidence accumulation

Hudai Fu*, Jingang Gao

School of Mechatronics Engineering, Changchun Institute of Technology, Changchun 130012, JiLin, China

Received 1 July 2014, www.cmnt.lv

Abstract

The traditional circle detection algorithm has complex computation, large memory space occupation and other deficiencies. It has low detecting efficiency and not suitable for the multi circle detection. So it proposes a multi circle detection method based on global search and evidence accumulation in the paper. The evidence accumulation and the weighted average are combined in the algorithm. The pseudo centre processed during the evidence accumulation are classified and analysed. Three kinds of pseudo centres are eliminated by class. Finally, the other circle parameters are calculated. It is proved that the algorithm has high precision, high efficiency, and low sensitivity to the defect of local information. Also the detecting time will not increase with the number of circles. The multi circle detection effect is obviously superior to the traditional randomized circle detection algorithm.

Keywords: Multi Circle Detection, Global Search, Evidence Accumulation

1 Introduction

Circle is one of the basic geometries in image analysis. The relevant information of the circles in image is required to rapidly detect in many fields, such as quickly detecting the location and size of round holes in the part, detecting round PCB printing plate in industry and so forth. Therefore, the circle detection has special significance in image analysis, pattern recognition and computer vision [1, 2].

The methods such as standard Hough transform (SHT) are commonly used to detect the circles [3]. It needs complex computation and large memory space, on account of using "one to many" mapping. Also it is not good at multi circle detecting. In recent years, the domestic and foreign scholars have done some researches in multi circle detection methods [4]. Xu presented randomized Hough transform (RHT), which took "many to one" mapping [5, 6]. It avoided huge amount of calculation comparing to SHT. But the sampling without targets could cause a large number of invalid samplings and invalid accumulations. So the performance of the algorithm was reduced. In addition, Chen proposed a randomized circle detection algorithm (RCD) not in RHT series [7]. The detecting speed was faster than RHT in the case of below medium noise ratio.

RCD detection algorithm and Hough transform have many problems in practical application. The probability of invalid sampling is great in multi circle detection. And the efficiency of the algorithm is low, because there are many square and square root operations in it. The test results have greater offset, because the threshold parameters have been set are different in both algorithms. The detecting speed will suffer great interference when the circle is incomplete, the image has large disturbances and so on. Therefore, a circle detection method based on global search is proposed. The evidence accumulation and the weighted average are combined in the algorithm. The pseudo centre processed during the evidence accumulation are classified and analysed. Three kinds of pseudo centres are eliminated by class. Finally, the other circle parameters are calculated.

2 Algorithm principle

2.1 GLOBAL SEARCHING CENTRE COORDINATE

Please see Figure 1. Suppose that the image size is M pixel× N pixel. After edge detection, there is

$$I(x,y)=\begin{cases}255, & if\\ 0, & else\end{cases}, \tag{1}$$

where $I(x,y)$ $(0\le x<M, 0\le y<N)$ is the grey value of row x the column y in the image.

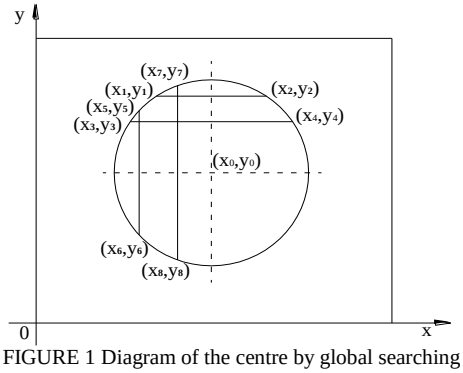

FIGURE 1 Diagram of the centre by global searching

Two arrays a_{2M} and b_{2N} are created. The position of each element in the array corresponds to the pixel coordinate of the centre. The size of the element stored in

* ***Corresponding author*** e-mail: fuhudai@126.com

the array is namely the evidence accumulation value of the corresponding pixel becoming the centre. Searching the coordinates of the centre consists of the following steps.

First, the pixels in the first row are searched. The horizontal ordinate average of each edge pixel and its nearest edge pixel is calculated successively. The value $a[2\times p_x]$ in the array a_{2M} will be added 1 after calculating one average value p_x each time. Then the pixels in each column will be processed as the above steps. The value $b[2\times p_y]$ in the array b_{2N} will be added 1 after calculating one average value p_y each time. See Equation (2).

$$\begin{cases} a[i]=a[i]+1 & if \quad i_1+i_2=i \\ b[j]=b[j]+1 & if \quad j_1+j_2=j \end{cases}. \tag{2}$$

In Equation (2), i_1, i_2 are the horizontal ordinates of the two adjacent pixels; j_1, j_2 are the vertical ordinates of the two adjacent pixels; and i, j is the position of the corresponding array element.

After completing global searching, the threshold T is set. The values in two arrays will be respectively compared with the threshold *T*. The position of the element which is greater than T in the array a_{2M} is twice of the centre abscissa value. And the position of the element which is greater than T in the array b_{2N} is twice of the centre ordinate value.

The evidence accumulation value in the array reflects the probability of each coordinate value taken as the centre coordinate, because of the symmetry of the circle. Since the accumulation value is gotten from calculating the average of the adjacent pixels, it has high degree of distinction, and the other kinds of edge interference can be effectively removed.

2.2 CHARACTERISTIC ANALYSIS OF PSEUDO CENTRE

For the multi circles detection, a variety of pseudo centres will be emerged after completing evidence accumulation. Because the digital image is in single pixel, the evidence accumulation values of the two adjacent coordinates in one circle are both greater than the set threshold, and they are not much difference. So the pseudo centre is produced. Please see Figure 2.

Pseudo centre can be divided into three categories:

1) Type 1 pseudo centre. Because the abscissa and ordinate values obtained from the evidence accumulation have many different combinations, as well as the adjacent coordinate probably can generate pseudo centre, one horizontal coordinate value can correspond multiple possible vertical coordinate values. The resulting multiple pseudo centres such as A C, E, F, G, H are shown in Figure 2.

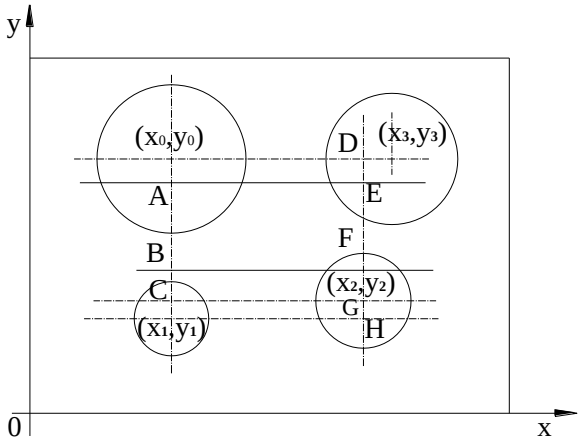

FIGURE 2 Diagram of pseudo centre

2) Type 2 pseudo centre. There will be a vertical coordinate value having larger evidence accumulation value between the two circles, if the centre horizontal coordinate values of the two circles are equal. This point is obtained from the evidence accumulation of the lower edge in the above circle and the upper edge in the below circle. Similarly, there will be a horizontal coordinate value having larger evidence accumulation value between the two circles, if the centre vertical coordinate values of the two circles are equal. Point B is this type of pseudo circle. Please see Figure 2.

3) Type 3 pseudo centre. The circles corresponding to (x_2, y_2) and (x_3, y_3) are shown in Figure 2. If the range of the two circles has larger overlap in the abscissa, the evidence accumulation values of (x_2, y_2) and (x_2, y_3) are both large, when doing evidence accumulation along the y axis for the edge points near x_2 and x_3. x_3 has the same situation. Also, the similar situation will also appear, if the range of the two circles has larger overlap in the ordinate. Point D is this type of pseudo circle. Please see Figure 2.

For type 1 pseudo centre, the vertical coordinate value corresponding to each horizontal coordinate can be found, only to do evidence accumulation for the edge points nearby every possible horizontal coordinate value along the vertical coordinate.

However, type 2 pseudo centre is not in the circle. The edge points nearby every possible horizontal coordinate value along the vertical coordinate are scanned. So the vertical coordinate of the edge point when doing evidence accumulation to the vertical coordinate of type 2 pseudo centre must vary greater, the further it is from the horizontal coordinate value. Type 2 pseudo centre can be eliminated according to this characteristic.

The vertical coordinate of type 3 pseudo centre (such as point D in Figure 2) is scanned. The difference of the edge points is great, when doing evidence accumulation to the vertical coordinate of point D on both sides of x_2. So, type 3 pseudo centre can be eliminated.

2.3 ELIMINATING PSEUDO CENTRE

According to the analysis in Section 2.2, all kinds of pseudo centre will be respectively eliminated.

1) Eliminating the adjacent centre and type 1 pseudo centre

The adjacent coordinate points have been found out by scanning the horizontal and vertical coordinates. The larger point of the evidence accumulation values is selected. If the difference between them is very small, the average of two points is taken as the centre coordinate. Setting thresholds t_1 and t_2, and the pixels of $2t_1+1$ columns from column (x_0-t_1) to column (x_0+t_1) are selected. The pixels per column are processed according to the method in section 2.1.

$$b[j]=b[j]+1, \tag{3}$$

if $j_1+j_2=j$ and $(x_0-t_1)\le i_0\le(x_0+t_1)$, where j_1 and j_2 are the vertical coordinate values of the nearest edge point in column i_0, and $b[j]$ is the evidence accumulation value for the vertical coordinate j. The vertical coordinates whose evidence accumulation value is greater than the threshold t_2 are the probable vertical coordinates $y_0^{'}, y_1^{'}\cdots$ corresponding to x_0. The vertical coordinate values of the edge points among the possible vertical coordinate values are recorded. Six pseudo centres including A, C, E, F, G, H can be eliminated, after x_0, x_1, x_2 have been processed in order.

2) Eliminating type 2 pseudo centre

The edge points carried out the evidence accumulation to the longitudinal coordinate $y_0^{'}$ are gathered in point group $C_{y_0^{'}}$. The maximum longitudinal coordinate point in column (x_0-t_1) or column (x_0+t_1) among the point group is chosen. If the ordinate of the point is larger than that of the maximum ordinate point in column x_0, it is the pseudo centre. The pseudo centre B can be eliminated, after x_0, x_1, x_2 have been processed in order.

3) Eliminating type 3 pseudo centre

In point group $C_{y_0^{'}}$, the longitudinal coordinate value which is greater than $y_0^{'}$ subtracts the one less than $y_0^{'}$ from column (x_0+1) to column (x_0+t_1), and the subtraction result is added up. Accordingly, the longitudinal coordinate value, which is greater than $y_0^{'}$ subtracts the one less than $y_0^{'}$ from column (x_0-t_1) to column (x_0-1), and the subtraction result is added up. Finally, the two calculated sums are subtracted.

$$\delta_0=\sum_{x_0+1}^{x_0+t_1}(y_i-y_{\ j})-\sum_{x_0-t_1}^{x_0-1}(y_k-y_{\ l}) \quad (y_i,y_{\ j},y_k,y_{\ l}\in C_{y_0^{'}}). \tag{4}$$

In equation (4) y_i is the ordinate value greater than $y_0^{'}$ from column (x_0+1) to column (x_0+t_1) in point group $C_{y_0^{'}}$, and y_j is the ordinate value less than $y_0^{'}$. y_k is the ordinate value greater than $y_0^{'}$ from column (x_0-t_1) to column (x_0-1) in point group $C_{y_0^{'}}$, and y_l is the ordinate value less than $y_0^{'}$. All possible ordinate values are calculated in turn by using equation (4). The corresponding differences having been gotten are $\delta_0,\delta_1,\cdots$. The threshold ε is set. The point whose difference δ is greater than the threshold ε will be eliminated. The pseudo centre D can be eliminated, after x_0, x_1, x_2 have been processed respectively.

So far, the pseudo centres corresponding to the abscissa x_0, x_1, and x_2 have been all eliminated. Similarly, the abscissa x_3 and the ordinate values $y_0,y_1\cdots$ can be processed as the above. The centre coordinates corresponding to it can be found. Finally, the evidence accumulation values of the true centre and its 8 adjacent points are taken as the weight. The coordinate values are carried out the weighted average, and the centre coordinates are gotten.

2.4 CALCULATING THE RADIUS

The images often have all kinds of noises in the actual industry detecting. In order to avoid noise interference, cluster analysis and the weighted average are used to minimize the error. The distance L from each edge pixel to the detected centre is calculated. The pixels close to the distance L are gathered as a class. Then the threshold ξ is set, the point group $C_{\max}$ gathered most points in the range of 2ξ is selected. The equation for calculating the weighted average of the radius is as follow. Please see Equation 5.

$$\sum_{L_n\in C_{\max}}\frac{P_n}{P_{sum}}L_n=L, \tag{5}$$

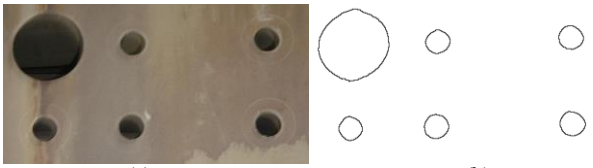
where L_n is the distance between the edge point and the centre in class $C_{\max}$. P_{sum} is the total number of points in class $C_{\max}$. P_n is the number of edge points whose distance is L_n in class $C_{\max}$. The value L calculated by equation (5) is the radius.

The clustering method can give full play to the effect of the evidence accumulation. The result can effectively avoid deviating from the correct value. The weighted average method used to calculate the radius can reduce

the inherent pixel error in digital image, and improve the reliability and accuracy of detection.

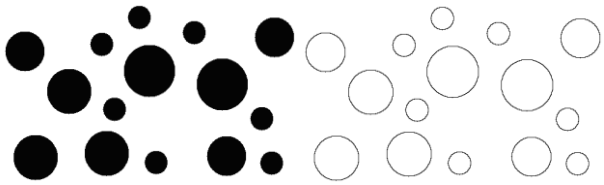
3 Experiment results and analysis

Please see Figure 3 (a) and Figure 4 (a). The sizes of the two experimental images are both 280pixel×166 pixel. First, an array *a*[560] and *b*[332] are created and initialized, and the parameter values $T=4$, $\varepsilon=2$, $\xi=0.5$, $t_1=4$ and $t_2=5$ are set. The proposed algorithm in the paper is used to separately detect the circles in two images. Please see Figure 3 (b) and Figure 4 (b).Then RCD algorithm is used to separately detect the circles in two images. The above two detections are carried out in the same hardware experiment environment.



(a) (b)

FIGURE 3(a) Automobile part image. (b) Proposed algorithm multi circle detecting result



(a) (b)

FIGURE 4(a) Experimental image. (b) Proposed algorithm multi circle detecting result

The comparisons of detected value and real value of Figure 3(a) are shown in Table 1.The error between the test results by the proposed algorithm and the real value is less than one pixel. Its accuracy is obviously superior to the RCD method. Please see Table 2. When the number of the circles increases, the executing time of RCD algorithm obviously increases. However, the executing time of the proposed algorithm is almost unchanged.

4 Conclusion

The experiment and analysis showed that the proposed algorithm had better performance than the traditional circle detection algorithm. First, it avoids the shortcoming of largely invalid random sampling probability in RHT and RCD algorithms, because the proposed algorithm applied the global search to the image. Secondly, it used the simple averaging operation instead of the square and square root operations in the traditional algorithm, and increased the efficiency of the algorithm. Again, it adopted the evidence accumulation combining with the weighted average to calculate the parameters of the circle, and improved the stability and accuracy of the results. It is proved, that the proposed algorithm had fast detection speed, high precision, and great practical value after detecting multiple images.

Applications of dynamic adaptive bee colony algorithm in multi-threshold image segmentation

Ye Chen*, Xiaoqun Qin

School of Information Science and Engineering, Hunan International Economics University, Changsha 410205, Hunan, China

Received 1 July 2014, www.cmnt.lv

Abstract

Artificial bee colony (ABC) is an evolutionary computation method, which is inspired from the specific collaborative social group behaviour among the individual bees in the colony and which is a heuristic optimization algorithm based on population search strategy. This paper has proposed a quick dynamic adaptive bee colony algorithm, which analyses the performances of the artificial bee colony algorithm and it designs a multi-threshold image segmentation method realizing a dynamic adaptive artificial bee colony (DAABC) with multi-threshold OTSU as the fitness function. The main characteristics of this method include: reducing the noise interferences in the multi-threshold image segmentation; effectively narrowing down the search range of the threshold; guaranteeing the quickness of the segmentation speed; determining the search range of the reconnaissance ants with adaptive dynamic control and accelerating the convergence speed of bee colony algorithm. The experimental results demonstrate that the method in this paper is better than the image segmentation method based on particle swarm optimization (PSO) and artificial fish swarm algorithm (AFSA).

Keywords: Artificial Bee Colony Algorithm, Multi-Threshold, Image Segmentation, OTSU

1 Introduction

ABC is a newly-emerging intelligent heuristic algorithm, which was proposed by Professor Karaboga in Erciyes University in 2005 and it comes from the research and simulation of honey-collecting behaviour of the bees. Compared with PSO, ant colony optimization (ACO) and differential evolution (DE), this method has simple operations, fewer parameters and strong robustness; therefore, it has attracted extensive attention of domestic and international scholars and it has successfully settled numerous practical problems. However, since ABC hasn't appeared until the recent years, it still has a short development history and there are still many problems to be solved, including the weak theoretical support, the critical times setting of the appearance of reconnaissance bee and the search behaviour of the honey-collecting bees.

The improvements of ABC mainly include the following three aspects: (1) the improvements of the search behaviour of the honey-collecting bees, including the suppression of bad food sources from becoming the neighbourhood bees and the accelerated movements the honey-collecting bees make on the excellent food sources; (2) the replacements of bad food sources. In the population evolution, replace the bad food sources in a narrow space in every circle to improve the quality; (3) the improvements of the appearance of the reconnaissance bees. In a new search, since the food sources which have been abandoned for too many retention times have been differentiated for the position in the population, adopt reverse learning strategy if it is global optimal; otherwise, cross them with better food sources[1].

In recent years, OTSU based on the maximum between-cluster variance has been successfully used in image dual threshold segmentation. This paper realizes multi-threshold image segmentation with OTSU. Additionally, it has used it in the artificial bee colony search algorithm and proposed a dynamic adaptive bee colony algorithm to analyse the value and status of bee colony algorithm in multi-threshold image segmentation.

2 The construction of the objective function in multi-threshold image segmentation

2.1 THE CONSTRUCTION OF OBJECTIVE FUNCTION

Firstly, assume that a grey-scale image can be shown with L grey scales ($L \in [1,256]$); the possibility for the pixel with i grey scales is $P_i(P_i = \frac{f_i}{N}, P_i > 0, \sum_{i=1}^{L} P_i = 1)$; f_i is the sum of the pixels with i grey scales and N is the total pixels of the image. If the threshold t segments the image l into the objective and the background, then the possibilities of the objective and the background are ω_0 and $\omega_1(t)$ separately and the mean value of the objective and the background are $\mu_0(t)$ and $\mu_1(t)$ and $\omega_0 + \omega_1 = 1$.

* ***Corresponding author*** e-mail: 153569367@qq.com

In the above formula, $\omega_0 = \sum_{i=0}^{t} P_i$, $\omega_1(t) = \sum_{i=t+1}^{L-1} P_i$, $\mu_0(t) = \sum_{i=0}^{t} iP_i / \omega_0$ and $\mu_1(t) = \sum_{i=t+1}^{L-1} iP_i / \omega_1$, $\omega_0 = \sum_{i=0}^{t} P_i$, $\omega_1(t) = \sum_{i=t+1}^{L-1} P_i$, $\mu_0(t) = \sum_{i=0}^{t} iP_i / \omega_0$, $\mu_1(t) = \sum_{i=t+1}^{L-1} iP_i / \omega_1$. Then the difference between the objective and the target is: $D(t) = \omega_0(t)\omega_1(t)(\mu_0(t) - \mu_1(t))^2$. Therefore, t with the biggest difference is the optimal threshold.

As mentioned above, assuming that the thresholds of the image to be segmented are m, then its difference is:

$$\begin{aligned} D(t_1, t_2, \ldots, t_m) &= \omega_0\omega_1(\mu_0 - \mu_1)^2 + \omega_0\omega_2(\mu_0 - \mu_2)^2 \\ &+ \cdots + \omega_0\omega_m(\mu_0 - \mu_m)^2 + \omega_1\omega_2(\mu_1 - \mu_2)^2 \\ &+ \omega_1\omega_3(\mu_1 - \mu_3)^2 + \cdots + \omega_{m-1}\omega_m(\mu_{m-1} - \mu_m)^2 \end{aligned} \quad . \quad (1)$$

In the formula, $\omega_{m-1} = \sum_{i=t_{m-1}+1}^{t_m} P_i$ and $\mu_{m-1} = \sum_{i=t_{m-1}+1}^{t_m} iP_i / \omega_{m-1}$. Assuming the segmentation threshold of the image is $(t_1^*, t_2^*, \ldots, t_m^*)$, then the optimal threshold of the image to be segmented is $(t_1^*, t_2^*, \ldots, t_m^*) = \underset{0 \le t_1 \le t_2 \ldots \le t_m}{Arg \max} D(t_1, t_2, \ldots, t_m)$ from the below formula according to DAABC [2, 3].

2.2 THE FEASIBILITY ANALYSIS OF THE OBJECTIVE FUNCTION

In the swarm intelligent optimization algorithm, the fitness function has a significant importance on the population optimization and it guides the population to forage or evolve towards a certain direction and finally reaches the optimal status.

This method sees the image threshold as the bee of the ABC and designs the fitness function of ABC through two-dimensional OTSU and it gets closer to the optimal threshold generation by generation through the collaboration and information share of the honey-collecting bees, the reconnaissance bees and the observing bees [4].

ABC searches the optimal nectar source through the collaboration and information share of the honey-collecting bees, the observing bees and the reconnaissance bees. The following analyses the working mechanism of the bee population by integrating the application environment of this paper. When ABC is used in the image segmentation, every nectar source position corresponds to a threshold and the honey volume of the nectar source corresponds to the fitness function value. The honey-collecting bee produces and compares a new position by searching the neighbourhood according to its memory. If the new position is superior to the optimal position in memory, replace it with the new position; otherwise, keep the original optimal position [5]. After all the honey-collecting bees finish searching, they share and nectar source information with the observing bees through "swing dance" and then the observing bees choose a nectar source position with the possibility related to the honey volume according to the information obtained and search and produce a new position by searching near the nectar source. After that, they compare with the previous position and always remember the optimal position. If a nectar source can't be improved through limited circulations, then abandon it and use the new position randomly producing by the reconnaissance bees [6].

In the bee colony search algorithm, the number of nectar sources can be seen as the number of thresholds of the image to be segmented, namely the number of variables of OTSU function. Every nectar source is deemed as the possible threshold of the image, namely the parameter $(t_1, t_2, \ldots, t_m)$ of OTSU function and when segmented 256-greyscale image, $(t_1, t_2, \ldots, t_m)$. Therefore, the objective function of the multi-threshold segmentation in (1) in this paper can be used as the fitness function of the bee colony search algorithm and the process to get a group of optimal parameters of multi-threshold OTSU function by using bees to find the optimal nectar source is the process to find the maximum value of Formula (1). In this way, it is feasible for the artificial bee colony search algorithm to be applied in the multi-threshold image segmentation [7, 8].

3 The analysis of segmentation object

Choose 4 commonly-used standard test images: Railway, Skyscraper, Bridge, Sunshine and woods, as the images to be segmented. The following are the grey-scale histograms of the 4 images. Analyse their histogram features.

FIGURE 1 Railway

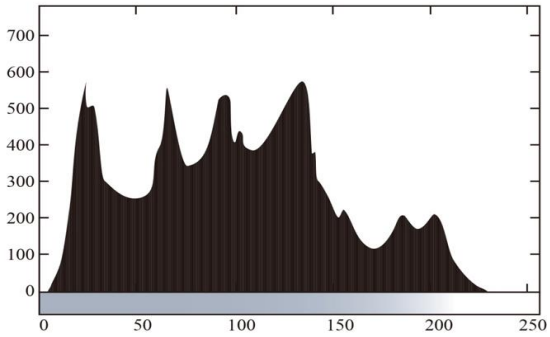

TABLE 1 The Histogram of Fig.1

FIGURE 2 Skyscraper

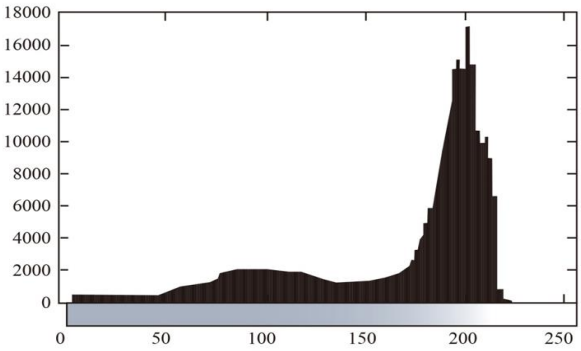

TABLE 2 The Histogram of Fig.2

FIGURE 3 Bridge

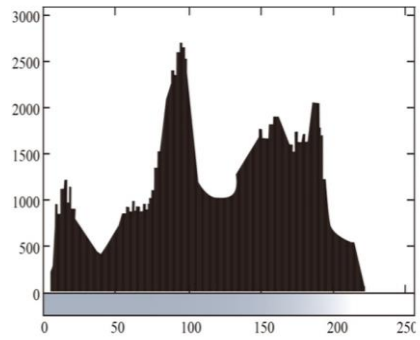

TABLE 3 The Histogram of Fig.3

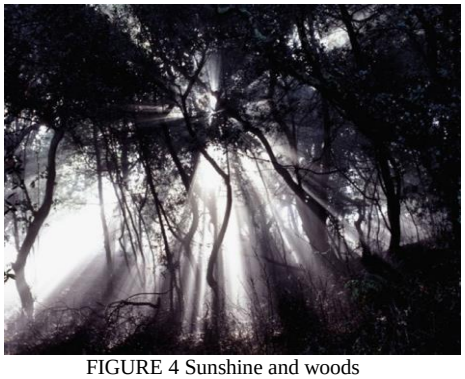

FIGURE 4 Sunshine and woods

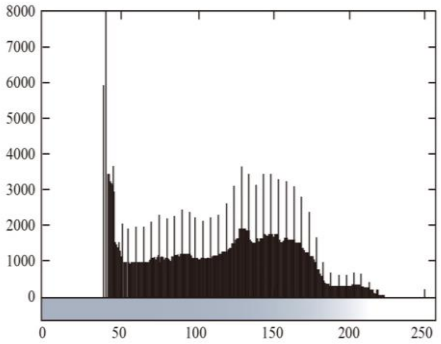

TABLE 4 The Histogram of Fig. 4

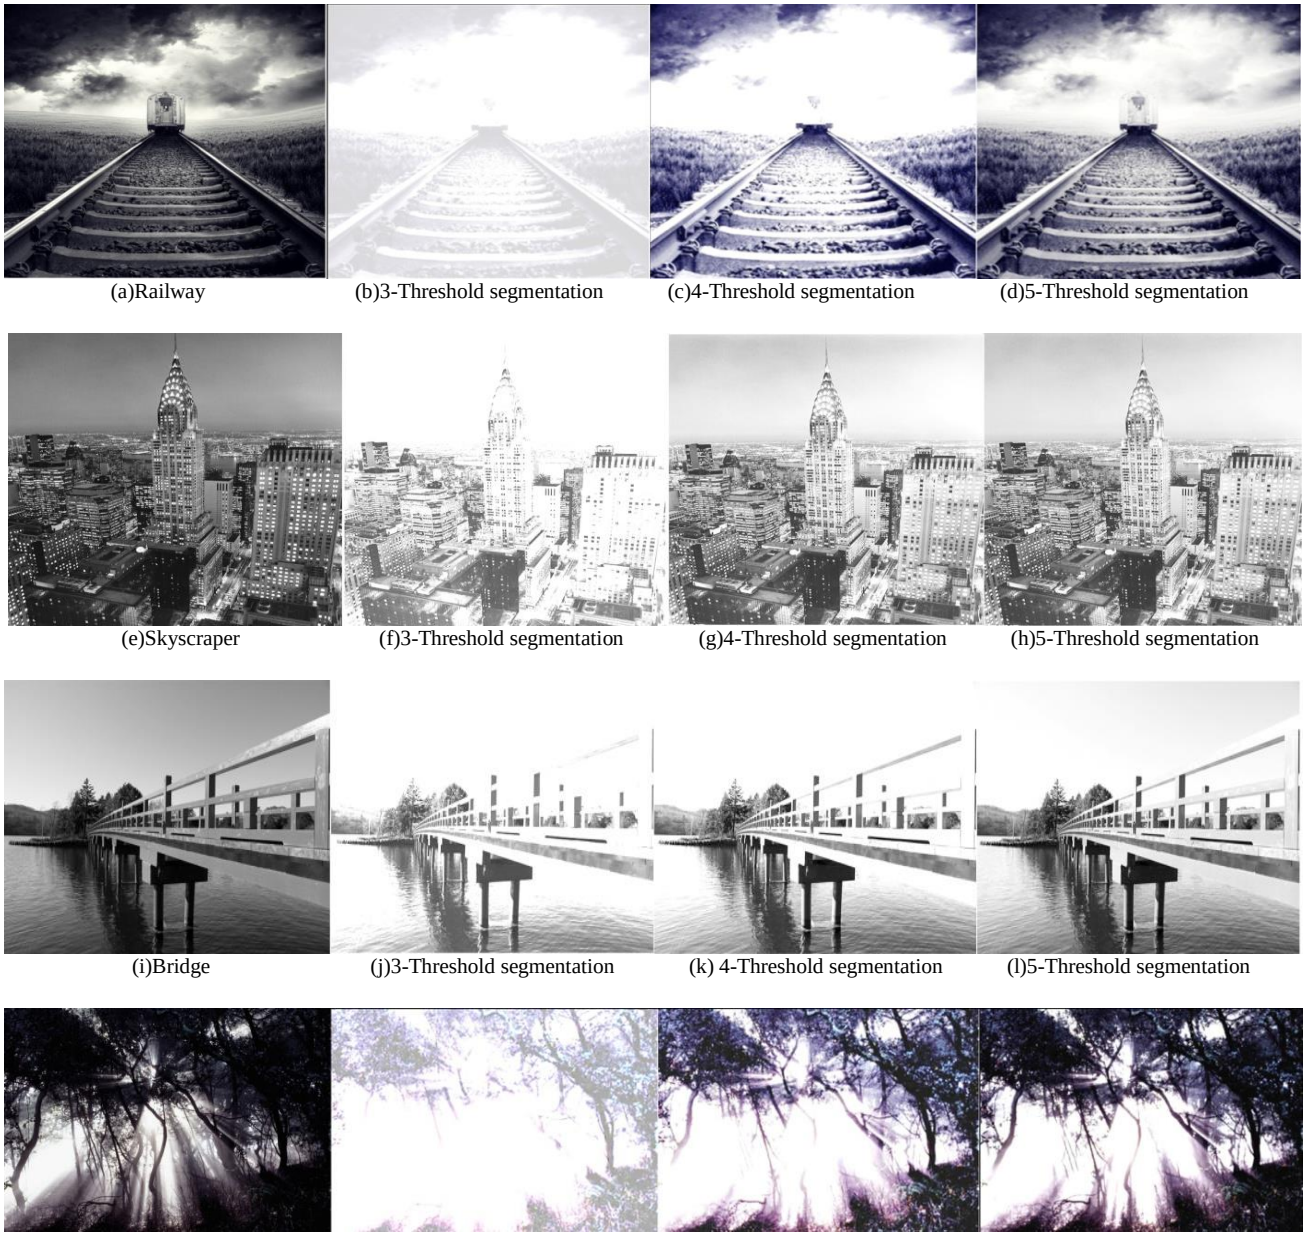
It can be seen that the histograms of the chosen standard test images from Table 1 to Table 4 have multiple peaks instead of only two peaks. The image histogram directly reflects the grey-scale distribution of the pixel points in the image; while single threshold can only segment the images with only two peaks in the histograms. Therefore, the previous single threshold segmentation method cannot precisely segment the images from Fig.1 to Fig.4 and only multi-threshold segmentation methods can be used to get ideal segmentation results.

4 Experimental analysis

In order to verify the effectiveness of DAABC in multi-threshold image segmentation, compare the performances of DAABC, PSO and basic AFSA in multi-threshold image segmentation with the above 4 standard test images as the images to be segmented and starting from the segmentation effects, segmentation speed and the quality of the optimal solutions.

4.1 THE COMPARISON OF SEGMENTATION RESULTS

With Formula 1 as the fitness function, obtain the 3-threshold, 4-threshold and 5-threshold of the above 4 standard test images through DAABC and get their segmentation images. As indicated in Fig.7, the left are the standard test images while the rights are their 3-threshold, 4-threshold and 5-threshold segmentation images successively.



(a)Railway (b)3-Threshold segmentation (c)4-Threshold segmentation (d)5-Threshold segmentation

(i)Bridge (j)3-Threshold segmentation (k) 4-Threshold segmentation (l)5-Threshold segmentation

(m)Sunshine and woods (n)3-Threshold segmentation (o)4-Threshold segmentation (p)5-Threshold segmentation

FIGURE 5 The results of segmentation image by DAABC

As shown in Fig.5, with the increase of the segmentation thresholds, the segmentation image is closer to the original image with better quality by integrating human visual features and comparing them with the original images. It is certain that if the threshold number of the segmentation image is closer to the number of the bottoms in the grey-scale histogram of the original images, the segmentation image is closer to the original image.

4.2 THE COMPARISON OF SEGMENTATION SPEED

In the operating environment of MATLAB, compare the performances of DAABC, PSO and AFSA in multi-threshold segmentation. Set the parameters of the 3 algorithms as follows: iterations: 50; population scale: 30 and fitness function: OTSU.

TABLE 5 The comparison of computation time of 3 swarm intelligent optimization algorithms (Unit/S)

Fig.5	M	DAABC	PSO	AFSA
(a)	3	8.5718	19.5173	13.5714
	4	10.1306	19.4181	12.8185
	5	10.7585	21.3673	15.3728
(e)	3	9.6138	19.5286	13.3185
	4	10.1582	19.6196	12.8396
	5	11.35518	20.1467	15.8179
(i)	3	10.9327	17.2868	12.5261
	4	11.6384	20.3628	15.9383
	5	10.7386	18.9515	15.2693
(m)	3	9.6281	20.7295	12.5718
	4	11.5795	19.5383	13.4156
	5	10.6215	20.3572	16.8627

Run the procedures 50 times and the time the 3 algorithms need to find the optimal threshold is as indicated in Table 7. According to this table, the order of optimization speeds of the 3 algorithms is DAABC>AFSA>PSO with the same thresholds. This is because bee colony algorithm is an algorithm of positive feedback and it is the most important link for the bees to exchange information. The dancing area is the most important information exchange place in the honeycomb. The bee dance is called swing dance. The information of the food sources is shared with other bees through swing dance in the dancing area and it leads the bees to show the yield rate of the food sources through the swing dance time; therefore, following the bees can observe many dances and choose which food source to collect the honey according to the yield rate. The yield rate is proportional to the possibility to be chosen. Therefore, the possibility the bees are recruited to a certain food source is in proportion to the yield rate of the food source. This positive feedback process leads the entire system to evolve towards the optimal solution. Therefore, positive feedback is an important characteristic of bee colony algorithm and it promotes the algorithm evolution to proceed.

It is remarkable that when segment the same image with the same algorithm of different thresholds, the time increases with the increase of thresholds because with the increase of the thresholds, the dimensions of the problems increases, thus increasing the time complexity of the algorithm.

4.3 THE COMPARISON OF QUALITY OF OPTIMAL SOLUTION

Set the same parameters as 4.2 in this paper. Run the procedures for 50 times and the results the optimal fitness function value and the optimal threshold are indicated as Table 7.

The fitness function demonstrates the difference between the target and the background. The bigger, the better. From Table 8, it can be seen that the order of the solution quality of the 3 algorithms is DAABC>AFSA>PSO on the same image with the same thresholds. Its reason is that as a parallel algorithm in nature, bee colony algorithm can be seen as a distributed multi-agent system. It has more points in the problem space and it conducts independent solution search, which not only increases the reliability of the algorithm, but also makes the algorithm have strong global search capacity. Besides, it can not only expand the search range and increase population diversity, but it is also easier to jump out of the local optimal point.

5 Conclusion

This paper has introduced the dynamic adaptive bee colony algorithm into the multi-threshold image segmentation; design multi-threshold fitness function with OTSU and guides the bee colony to quickly find the optimal segmentation threshold. By testing the standard images and comparing the optimization performance of the other two swarm intelligent algorithms, the experimental results show that the algorithm in this paper has faster optimization speed and high optimization quality compared with the other two swarm intelligent algorithms on the same images to be segmented with the same thresholds.

Abstract

With the growth of Linked Open Data, more and more applications are developed to take full advantage of its massive data. However, all these applications face an inevitable problem - how to retrieve information from these datasets with different schemas, which results in that a query for a dataset may get none answer from other datasets. To solve this problem, ontology alignment has been adopted in some Linked Open Data querying systems. In this paper, we follow this idea and make further efforts to find more approximate answers by employing relations and probability values in the result of ontology alignment. The fundamental of our method is the similarity between entities, which is used to evaluate the similarity of rewritten query relative to original query. In order to facilitate user to query other dataset with original query, an algorithm for alignment-based approximate querying is proposed. In experiments, the SPARQL queries for DBpedia are rewritten on the basis of alignment result between DBpedia and YAGO. The results of experiments show that alignment-based approximate querying can not only retrieve approximate results, but also overcome the problem caused by imprecise result of ontology alignment, which is very common for most of alignment techniques.

Keywords: Linked Open Data, Approximate Querying, Ontology Alignment, SPARQL

1 Introduction

Since the W3C Linked Open Data (LOD) project launched in 2007, more and more datasets were published in the web of Data, which have covered a diversity of areas such as nature, geography, government, and so on. It offered a great incentive for researchers to develop various applications based on the LOD. The Traffic LarKC combined DBpeida, a central part of LOD, with an eventful wrapper and datasets of two Milano municipalities to implement an intelligent question answering system about the traffic [1]. On the basis of information theory, Meymandpour R. et al. took advantage of LOD in the domain of university to rank universities and compare the results with the international ranking system [2]. Obviously, the inevitable problem for those applications is how to retrieve information form the LOD efficiently.

There are several approaches to query the LOD and each of them has its own advantages and limitations [3]. Data warehouses and query federation, two traditional approaches for query answering over distributed data, can be employed to execute the complex and structured queries over LOD [4, 5]. The search engine for the LOD can retrieve the web by following RDF links and provide query interfaces for users to search information in the LOD, just as Sindice [6]. In contrast to above methods, traversal based query execution over LOD, a novel query execution paradigm, can intertwine query pattern matching over a continuously growing dataset with the traversal of links in order to discover data that might be relevant to answer the executed query [7]. However, no matter what approach the user adopts, the query patterns must be provided in advance, that means the user should be familiar with all schemas of the datasets he wants to query.

In fact, it is an impossible task for a user because the number of datasets in LOD increases continuously and each dataset always has a particular schema. For example, DBpedia [8] and YAGO [9] have their respective properties to express the relationships between the instances even if two properties have the same meaning, such as “geo:long” and “yago:hasLongitude” shown in Figure 1. Suppose a user want to query the information of longitude, latitude and population about the city Chengdu, the SPARQL query in formula (1)[1] can retrieve the results from DBpeida, but YAGO returns nothing because of the mismatches between query patterns and schemas of YAGO. Except for the above inconvenience, querying on a single dataset may lose the chance to get answer that exists in other datasets. In Figure 1, the property “dbo:capital” between “dbr:Sichuan” and “dbr:Chengdu” is not stated in DBpeida, so that the query pattern “dbr:Sichuan dbo:capital ?c” finds nothing in DBpedia. But, “yago:Sichuan yago:hasCapital ?c”, the query pattern with the same meaning, can make up for the

* ***Corresponding author*** e-mail: Chen_lei0605@sina.com

[1]All queries in this paper omit the definition of prefixes declared in Figure 1

discount in DBpeida by obtaining the answer from YAGO.

```
Select   ?lat     ?long    ?p
Where { dbr:Chengdu geo:lat ?lat.                    .        (1)
        dbr:Chengdu  geo:long ?long.
        dbr:Chengdu dbo:populationTotal ?p.}
```

In order to solve those problems, the approach that user can follow is ontology alignment. By combining the mechanism of query federation with the results of ontology alignment, an alignment based Linked Open Data querying system (ALOQUS) was proposed in [10]. It can map concepts in an upper ontology or domain specific ontology to concepts in other datasets, providing the capability to answer queries which cannot be answered by other state of the art system for LOD query processing. In this paper, we follow the idea of ALOQUA and make further efforts. Our method can find more approximate answers and overcome the problem caused by imprecise result of ontology alignment. The contribution of this paper is three-fold:

(1) We measure the similarity of rewritten query relative to the original query. The calculation of similarity depends on the result of ontology alignment, which include not only the relations between entities, but also the probability values of those relations.

(2) We propose an algorithm for alignment-based approximate querying, which can help user to query other dataset by using the original query and result of ontology alignment.

(3) We prove the validity of our approach through experiments on real-world datasets of LOD. The results show that alignment-based approximate querying can retrieve more answers.

The remainder of this paper is organized as follows. Section 2 discusses related work. In section 3, the SPARQL query rewriting is described with a formal way. How to calculate similarity between entities and queries on the basis of alignment result are explained in section 4. Section 5 proposes an algorithm for alignment-based approximate querying. The experiment results and their evaluations are presented in section 6. The conclusion of this paper is in section 7.

2 Related work

Hurtado et al. propose an RDF query relaxation method through RDF(s) entailment producing more general queries for retrieving potential relevant answers [11]. In order to ensure the desired cardinality and quality of answers, Huang et al. use the similarity between relaxed queries and original query to control the relaxation process [12, 13]. However, these works relax the original query based on a single schema, which is not suitable for various schemas of datasets in LOD. In [14, 15], Reddy et al. attempt to make use of ontologies available on the web of data to produce approximate answers, and integrate the approximate steps with query execution to improve the performance of query processing. Nevertheless, the similarity measure of relaxed SPARQL queries and the experiments in [14] are still based on the dataset with a single schema.

The purpose of ontology alignment is to find the sets of correspondences between entities belonging to the matched ontologies [16]. The result of ontology alignment is generated by hand or by ontology matchers and can be used for merging ontologies, linking datasets and transforming queries [17]. Just like ALOQUS introduced in [10], the best alignments in the result of BLOOMS mapping are used to transform the sub-queries, which are executed in the corresponding end-points later.

dbo: <http://dbpedia.org/ontology/> dbr: <http://dbpedia.org/resource/>
yago: <http://yago-knowledge.org/resource/>

FIGURE 1 An example of ontology alignment between DBpedia and YAGO

Here, BLOOMS is an ontology matcher for schema alignment and can find the relations of including and equivalence between the classes belonging to the matched ontologies [18]. In general, relations found by an ontology matcher have some associated metadata. A frequently-used metadata element is confidence in the correspondence (typically in the [0, 1] range). The higher confidence means the higher likelihood that the relation holds [19]. Some ontology matchers use probability to describe the likelihood of relation between the entities, such as probability scores in PARIS (Probabilistic Alignment of Relations, Instances, and Schema) [20]. PARIS is a holistic ontology matcher--aligning not only instances but also properties and classes, which is a significant feature that can be employed to transform queries. Figure 1 presents some alignment results of PARIS about properties and instances between DBpeida and YAGO (e.g. "geo:lat" is a sub relation of "yago:hasLatitude" with the probability score 0.79 (Although values presented in this paper only reserve two decimal fractions, the type of values is double in the implementation procedure of alignment-based approximate SPARQL query)). In this paper, we will take the most advantage of PARIS to implement the approximate SPAQRL querying on LOD.

3 SPARQL query rewriting

With the purpose of retrieving the data stored in RDF format, W3C proposed SPARQL. The fundamental component of SPARQL query is triple pattern, which can be expressed as $(s, p, o) \in (I \cup V) \times (I \cup V) \times (I \cup V \cup L)$. Here, V is a set of variables, I is a set of IRIs (Internationalized URIs), and L is a set of literals. In general, a SPARQL query is built on some triple patterns with series operations of conjunction and disjunction. It is worth noting that other components of SPARQL query are not mentioned here. It is because that they have little influence on the SPARQL query rewriting.

Given Q is a SPARQL query and all IRIs in triple patterns of Q come from the dataset $D1$, Q can be denoted as Q^{D1}, which means the Q is designed for $D1$ and may retrieve some results from $D1$. Because of the diversity of datasets in LOD, the execution of Q^{D1} on another dataset $D2$ may return nothing, just as the example introduced above. By replacing IRIs in triple patterns of Q^{D1} with IRIs in $D2$, the SPARQL query rewriting can generate some new queries (denoted as Q^{D2}) that have the same or similar meaning with Q^{D1}. Then, users do not have to know the schema of D2 to query it with Q^{D2}. For example, the query for DBpedia in formula (1) can be transformed to the query in formula (2), so that user can achieve the desired answers from YAGO. Despite having the significant advantage, the SPARQL query rewriting faces a vital problem--how to choose IRIs in $D2$ to replace the IRIs in Q^{D1}. Apparently, the high similarity between them is preferred.

```
Select    ?lat    ?long    ?p
Where { yago:Chengdu yago:hasLatitude ?lat.
        yago:Chengdu  yago:hasLongitude ?long.
        yago:Chengdu yago:hasPopulation ?p.}
```
. (2)

4 Alignment-based similarity

4.1 SIMILARITY BETWEEN ENTITIES

To compute the similarity of IRIs from two different datasets, the results of ontology alignment can be employed. The result of ontology alignment between $D1$ and $D2$ is a finite set S, including a certain number of 4-tuples. Formally, a 4-tuple can be written as $<e1, e2, r, p>$. Here, $e1$ and $e2$ are entities in $D1$ and $D2$ respectively, and r is the relation between $e1$ and $e2$, such as equivalence ($\equiv$), including ($\supseteq$), included ($\subseteq$), and etc. The true probability value of the relation between $e1$ and $e2$ is p, which ranges from 0 to 1. For example, the relations between "geo:lat" and "yago:hasLatitude" in Figure 1 can be expressed as $<geo:lat, yago:hasLatitude, \supseteq, 0.97>$ and $<geo:lat, yago:hasLatitude, \subseteq, 0.79>$. Nevertheless, $<dbo:shipBeam, yago:hasLatitude, \subseteq, 0.78>$ also is a part of result when user adopts PARIS to align DBpeida and YAGO. At this time, the SPARQL query rewriting needs to decide which property is more similar with "yago:hasLatitude".

Taking the diversity of 4-tuple into account, our method computes the similarity between entities according to different conditions. First, the relationship between instances is always equivalence, so similarity between $i1$ and $i2$ is p when S includes $<i1, i2, \equiv, p>$. Here, $i1$ and $i2$ are instances in $D1$ and $D2$ respectively. In Figure 1, $<dbr:Chengdu, yago:Chengdu, \equiv, 0.99>$ implies that similarity between "dbr:Chengdu" and "yago:Chengdu" is 0.99, indicated as

$$Sim(dbr:Chengdu, yago:Chengdu) = 0.99. \quad (3)$$

Second, class or property in dataset is usually viewed as a set that means r in 4-tuple could be any relations for set, which make the computation of similarity for them more complex than instance. For definiteness and without loss of generality, only computing methods for similarity between classes are introduced here. Given $c1$ and $c2$ are classes in $D1$ and $D2$ respectively, the similarity between two classes can be defined as:

$$Sim(c1,c2) = \frac{|c1 \cap c2|}{|c1 \cup c2|}, \quad (4)$$

where $|c1 \cup c2|$ is the cardinality of union of $c1$ and $c2$. It is clear that similarity between classes is in the [0, 1]. Suppose that the relation set of classes includes equivalence ($\equiv$), including ($\supseteq$) and included ($\subseteq$). Then, the calculations of similarity based on S are divided into the following cases:

(1) $<c1,c2,\equiv,p> \in S$. In this case, similarity between *c1* and *c2* is *p*.

Proof: Given *U* includes all instances of classes in *D1* and *D2*, and *x* is an element in *U*, then

$$P(c1 \equiv c2) = P(x \in c1 \cap c2 \mid x \in c1 \cup c2) = \frac{P(x \in c1 \cap c2)}{P(x \in c1 \cup c2)} = \frac{\frac{|c1 \cap c2|}{|U|}}{\frac{|c1 \cup c2|}{|U|}} = \frac{|c1 \cap c2|}{|c1 \cup c2|} = Sim(c1,c2) \quad (5)$$

(2) $<c1, c2, \supseteq, p1> \in S$ and $<c1, c2, \subseteq, p2> \in S$. In this case, similarity between *c1* and *c2* is

$$Sim(c1,c2) = \frac{p1 \cdot p2}{p1 + p2 - p1 \cdot p2}. \quad (6)$$

Proof: Given *x* is an element in *U*, then

$$P(c1 \subseteq c2) = P(x \in c1 \cap c2 | x \in c1) = \frac{|c1 \cap c2|}{|c1|}, \quad (7)$$

$$P(c1 \supseteq c2) = P(x \in c1 \cap c2 | x \in c2) = \frac{|c1 \cap c2|}{|c2|}, \quad (8)$$

Because $P(c1 \subseteq c2) = p2$ and $P(c1 \supseteq c2) = p1$, then

$$|c1| = \frac{|c1 \cap c2|}{p2}, \quad (9)$$

$$|c2| = \frac{|c1 \cap c2|}{p1}, \quad (10)$$

Now, bring formula (9) and (10) into the definition of similarity, the conclusion can be achieved with the following inference.

$$Sim(c1,c2) = \frac{|c1 \cap c2|}{|c1 \cup c2|} = \frac{|c1 \cap c2|}{|c1| + |c2| - |c1 \cap c2|} = \frac{|c1 \cap c2|}{\frac{|c1 \cap c2|}{p2} + \frac{|c1 \cap c2|}{p1} - |c1 \cap c2|} = \frac{p1 \cdot p2}{p1 + p2 - p1 \cdot p2}. \quad (11)$$

For example, *<dbo:School, yago:wordnet_school_108276720, ⊇ ,0.64>* and *<dbo:School, yago:wordnet_school_108276720, ⊆ , 0.78>* are in the result of ontology alignment when PARIS is adopted to align DBpedia and YAGO. Hence, the similarity between "dbo:School" and "yago:wordnet_school_108276720" is 0.54.

(3) $<c1, c2, \supseteq, p1>$ *S* or $<c1, c2, \subseteq, p2> \in S$. Since only one relation between two classes found by ontology matcher, formula (6) cannot be used directly in this case. For optimal performance, ontology matchers always set some thresholds to reduce the amount of computations, such as PARIS assumes every value below to be zero [20]. It means the probability of undetected relation may be a value below the threshold. In addition, there are some relations between including probability and included probability. Table 1 presents some super classes of "dbo:School" in YAGO, which are found by PARIS. Obviously, more general super classes of original class *c* is prone to have bigger value of included probability and leads to smaller value of including probability – and vice versa. In order to approximately simulate the above-mentioned relations between included probability and including probability, the formula (12) is adopted here.

TABLE 1 Some super classes of "dbo:Hospital" in YAGO

DBpeida	Relation	YAGO	Probability
dbo:School	⊆	yago:wordnet_senior_high_school_108409617	0.47
dbo:School	⊆	yago:wordnet_secondary_school_108284481	0.61
dbo:School	⊆	yago:wordnet_school_108276720	0.78
dbo:School	⊆	yago:wordnet_institution_108053576	0.78
dbo:School	⊆	yago:wordnet_educational_institution_108276342	0.78
dbo:School	⊆	yago:yagoLegalActorGeo	0.79
dbo:School	⊆	yago:wordnet_entity_100001740	0.80

$$P(c \supseteq x) = \begin{cases} \frac{T \cdot (max(c,\subseteq) - P(c \subseteq x))}{max(c,\subseteq) - min(c,\subseteq)} & max(c,\subseteq) \neq min(c,\subseteq) \\ T \cdot (1 - P(c \subseteq x)) & max(c,\subseteq) = min(c,\subseteq) \end{cases}. \quad (12)$$

Here, *T* is threshold value of including relation, which is the upper limit for including relation, *max(c, ⊆)* is the maximum probability value in the superclass set of *c*, *min(c, ⊆)* is the minimum probability value in the superclass set of c. For example, *max(dbo:School, ⊆)* is 0.80 and *min(dbo:School, ⊆)* is 0.47, just as shown in Table 1. Once $P(c \supseteq x)$ gets calculated, the similarity between *c* and *x* can be easily achieved by bringing $P(c \supseteq x)$ and $P(c \subset x)$ into formula (6).

In fact, the computation of included probability based on including probability can adopt the same mechanism, just as formula (13) shows. In the same way, *T'* is threshold value of included relation; *max(c, ⊇)* is the maximum probability value in the subclass set of c; *min(c, ⊇)* is the minimum probability value in the subclass set of c.

$$P(c \subseteq x) = \begin{cases} \frac{T' \cdot (max(c,\supseteq) - P(c \supseteq x))}{max(c,\supseteq) - min(c,\supseteq)} & max(c,\supseteq) \neq min(c,\supseteq) \\ T' \cdot (1 - P(c \supseteq x)) & max(c,\supseteq) = min(c,\supseteq) \end{cases}. \quad (13)$$

Although formula (12) and formula (13) are exactly similar, there are some tricks, that should be mentioned. For instance, *T* and *T'* are two key parameters, which

reflect the tendency of users for precision or recall. If *T'* is bigger than *T*, classes in subclass of *c* is prone to achieve higher similarity, that means these classes can take precedence to be selected during the process of query rewriting. Then, the precision of query results may increase according to the mechanism introduced in section 5.

4.2 SIMILAR ENTITIES RETRIEVAL

Based on the definition of similarity between entities, an algorithm is given here to obtain the similar entities of target entity. The steps of the algorithm consist of initialization, retrieval of similar entities, sorting the set of similar entities, and so on. The details of the algorithm are described as follows:

Algorithm SER
Input: an entity in original dataset *e*, a result set of ontology alignment *resultSet*, threshold value of including relation *T*, threshold value of included relation *T'*.
Output: a set of entity with similarity *similarSet*
1: Initialize *similarSet*
2: find equivalent set of *e* from *resultSet*, denoted as *equalSet*
3: find superclass set of *e* from *resultSet*, denoted as *superSet*
4: find subclass set of *e* from *resultSet*, denoted as *subSet*
5: for each *x* in *equalSet* do
6: push <*x*, *p*> into *similarSet* according to formula (5); Here, *p* is probability value, with which *e* equals with *x*.
7: end for
8: for each *x* in *superSet*
9: if x is not in *similarSet*
10: if x is in *subSet*
11: calculate the similarity *s* between *x* and *e* according to formula (6)
12: else
13: calculate the similarity *s* between *x* and *e* according to T, formula (12) and formula (6)
14: end if
15: push <*x*, *s*> into *similarSet*
16: end if
17: end for
18: for each *x* in *subSet*
19: if *x* is not in *similarSet*
20: calculate the similarity *s* between *x* and *e* according to *T'*, formula (13) and formula (6)
21: push <*x*, *s*> into *similarSet*
22: end if
23: end for
24: sort *similarSet* in descending order by similarity
25: return *similarSet*

4.3 SIMILARITY BETWEEN QUERIES

In general, a SPARQL query is composed of several triple patterns, so that the similarity between original triple pattern and rewritten triple pattern should be defined first. Suppose that $q^{D1}(s^{D1}, p^{D1}, o^{D1})$ is a triple pattern for the dataset *D1* and $q^{D2}(s^{D2}, p^{D2}, o^{D2})$ is a rewritten triple pattern for the dataset *D2*, and then the similarity between q^{D1} and q^{D2} can be calculated by using formula (14).

$$Sim(q^{D1}, q^{D2}) = \frac{1}{3}(Sim(s^{D1}, s^{D2}) + Sim(p^{D1}, p^{D2}) + Sim(o^{D1}, o^{D2})) \quad (14)$$

Considering Figure 1 and Algorithm SER, *Sim(dbr:Chengdu, yago:Chengdu)* is 0.99, *Sim(geo:lat, yago:hasLatitude)* is 0.77, and then *Sim("dbr:Chengdu geo:lat ?c", "yago:Chengdu yago:hasLatitude ?c")* is 0.92.
Given an original query $Q^{D1}(q_1^{D1}, q_2^{D1}, \cdots, q_n^{D1})$ consists of n triple patterns and $Q^{D2}(q_1^{D2}, q_2^{D2}, \cdots, q_n^{D2})$ is the rewritten query, then the similarity between Q^{D1} and Q^{D2} is

$$Sim(Q^{D1}, Q^{D2}) = \prod_{i=1}^{n} w_i \cdot Sim(q_i^{D1}, q_i^{D2}), \quad (15)$$

where $w_i \in (0,1]$ is the weight of triple pattern q_i^{D1}, which stands for the importance of q_i^{D1} in Q^{D1}, When the value of each w_i is set to 1, the similarity between formula (1) and formula (2) is 0.78.

5 Alignment-based approximate querying

On the basis of result of ontology alignment, alignment-based approximate querying can be implemented by executing the following procedures. At first, the query parser locates the entities in Q^{D1} that should be replaced later, and then puts them into a container for subsequent processing. It is obvious that variables and constants in Q^{D1} do not need to be added. Except for variables and constants, some IRIs that are widely used in most datasets should be skipped as well, such as "rdf:type", "owl:sameAs", and so on. In the second step, similar entities of each entity in the container are obtained by calling the algorithm SER. Then, some rewritten queries for the dataset *D2* can be constructed by replacing original entities with similar entities. During the construction procedure, subject and object should be upside down when the property in dataset D1 is replaced by inverse property. For example, "dbo:creator" and "yago:created" have an inverse relationship. After sorting rewritten queries in descending order by similarity, the query engine executes these rewritten queries on dataset *D2* one by one and records the query answers until the termination criterions are satisfied. In the following algorithm, the concrete termination criterions are not

given, because user can set particular criterions that fit the requirement of specific application. For some applications, it could be a reasonable termination criterion when top k of the most similar queries is executed on dataset *D2*. The details of algorithm for alignment-based approximate querying are described below.

Algorithm AAQ
Input: an query Q^{D1} for the dataset *D1*, a result set of ontology alignment *resultSet*, threshold value of including relation *T*, threshold value of included relation *T'*.
Output: a result set with similarity *queryResult*

1: Initialize *queryResult*
2: Initialize *sContainer*. Here, *sContainer* is a container that includes entities in Q^{D1} and their similar entity in dataset *D2*
3: locate entities in Q^{D1} that should be replaced
4: put these entities into a container, denoted as *eContainer*
5: for each *e* in *eContainer*
6: Initialize *similarSet*
7: *similarSet = SER(e, resultSet, T, T')*
8: put <*e, similarSet* > into *sContainer*
9: end for
10: *rqSet* = RewrittenQuery(Q^{D1}, *sContainer);* Here, the function RewrittenQuery is to construct similar queries; *rqSet* is a set that includes all rewritten query for dataset *D2*
11: sort *rqSet* in descending order by similarity
12: for each *q* in *rqSet*
13: if(terminationSatisfied())
14: break
15: end if
16: *tmpResult = Engine.query(q, D2)*
17: *queryResult.add(tmpResult)*
18: end for
19: return *queryResult*

By analysing the algorithm AAQ, it can be easily concluded that the size of rewritten query set is closely related to two factors--one is the number of entities that should be replaced; the other is the number of similar entities of each entity, which depends on the algorithm SER. Hence, the size of queryResult can be counted with Formula (16).

$$|queryResult| = \prod_{e \in eContainer} |SER(e,resultSet,T,T')| . \quad (16)$$

6 Experiments

To testify the availability of alignment-based approximate SPARQL query, two key datasets in LOD (DBpedia and YAGO) are chosen as testing data sets in this paper. The versions of datasets are the same as the datasets used in [20]. The experiments show that the version of YAGO in [20] has no information about "rdf:type" facts of YAGO, therefore we download taxonomy data from the official website of YAGO and combine them with the above datasets. All data are imported into Virtuoso, which is an efficient RDF triple store and provides SPAQRL query language support. Just as explained in section 2, the results of ontology alignment found by PARIS are employed to evaluate the similarity between entities and rewrite queries. In addition, *T* and *T'* are set to 0.3 and 0.1 respectively because they conform to the results of PARIS.

In experiments, we construct five SPARQL queries based on the schema of DBpedia, which are listed in Table 2. The purpose of these queries is to retrieve all instances of specified type and some attributes about them. For instance, No.1 query is to find population size and council area of settlements in DBpedia; No.2 query is to find latitude and longitude of schools in DBpedia. Table 3 presents some experimental results. Here, these queries for DBpedia produce plenty of similar queries for YAGO, such as No.3 query having 13675 rewritten queries, similarity of which range from 0.51 to 0.43. The main reason why No.3 query derives so many rewritten queries is that 13670 subclasses and 7 super classes of "dbo:Organisation" are found in the results of ontology alignment. It is not necessary to execute all rewritten queries on YAGO because some queries with low similarity may return lots of inaccurate results. In this paper, only top 10 of rewritten queries are executed on YAGO, and the last column of Table 3 shows the number of result, which do not take duplicate results into account. We also submit the original queries to DBpeida and count the number of result set respectively, which are listed in the column of "Result Number of Original Query on DBpedia". By comparing result numbers of original queries and rewritten queries, it can be concluded that rewritten queries can improve the recall to some extent.
The similarity and the result number about top 10 of rewritten queries are listed in Table 4, in which two characteristics should be noticed. The first one is that few queries in the front of list of rewritten queries have distinctive similarity. In the rewritten queries of No.4 query, the similarities of the first 3 rewritten queries are noticeably greater than others. That is because the entities replacing "dbo:GolfPlayer" in these rewritten queries have both including and included relations with "dbo:GolfPlayer" in the result of ontology alignment. "yago:wordnet_golfer_110136959", "yago:wikicategory_American_golfers", "yago:wikicategory_PGA_Tour_golfers" are these entities. Obviously, the rewritten queries with these entities are more likely to achieve greater similarity according to the computational method of similarity introduced in section 4. Second, the rewritten query with the greatest similarity may return nothing despite obtaining many results in most cases. In Table 4, No.3 query is a typical example. By executing the algorithm SER on the result of PARIS, it is found that the

similarity between "dbo:Organisation" and "yago:yagoLegalActor" is greater than the similarity between "yago:wordnet_organization_108008335" and "dbo:Organisation", which results in "yago:yagoLegalActor" is used to replace "dbo:Organisation" in the top 1 of rewritten queries of No.3 query. However, for literal meaning and answer size "yago:wordnet_organization_108008335" is a better substitute than "yago:yagoLegalActor". The same phenomenon happens on No.5 query. The causation of this phenomenon is that the result of ontology alignment is not absolute precision. It means that approximate query is more suitable for the information retrieval based on ontology alignment--because the rewritten query with the "most" similar entity may miss chance to find the information meeting requirements.

TABLE 2 Some SPARQL queries based on the schema of DBpedia

No.	Queries fo DBpedia
1	SELECT ?s ?p ?c WHERE {?s rdf:type dbo:Settlement. ?s dbo:populationTotal ?p. ?s dbo:councilArea ?c.}
2	SELECT ?s ?lat ?long WHERE { ?s rdf:type dbo:School. ?s geo:lat ?lat. ?s geo:long ?long.}
3	SELECT ?o ?c ?m WHERE { ?o rdf:type dbo:Organisation. ?c dbo:creator ?o. ?o dbo:motto ?m. }
4	SELECT ?g ?a WHERE { ?g rdf:type dbo:GolfPlayer. ?g dbo:award ?a. }
5	SELECT ?a ?n ?d WHERE { ?a rdf:type dbo:Artist . ?a dbo:notableWork ?n. ?a dbo:deathDate ?d }

TABLE 3 Some features of original queries and their rewritten query

No.	Number of Rewritten Query	Max of Similarity	Min of Similarity	Result Number of Original Query on DBpedia	Result Number of Top 10 of Rewritten Queries on YAGO
1	7500	0.52	0.41	495	210

7 Conclusion

Aiming at the problem that various schemas of datasets make it inconvenience to retrieve information from LOD, an approach of approximate SPARQL querying based on ontology alignment is proposed in this paper. On the basis of the formal result of ontology alignment, our approach quantitatively measures the similarity between entities in different conditions, and then the similarity between rewritten queries. Further, our approach can use these rewritten queries to obtain approximate answers from other dataset. The experiments show that alignment-based approximate SPARQL querying can not only retrieve approximate answers, but also overcome the problem caused by imprecise result of ontology alignment, which is very common for the techniques of ontology alignment. In the future work, we will improve alignment-based approximate querying from two aspects: one aspect is to increase the accuracy of ontology alignment between datasets in LOD; the other is to combine alignment-based approximate querying with other query execution paradigm, such as traversal based query execution over LOD [7].

A fractal de-noising algorithm based on least absolute deviation method

Hui Guo*, Jie He

School of Information and Electronic Engineering, Wuzhou University, Wuzhou 543002, Guangxi, China

Received 1 June 2014, www.cmnt.lv

Abstract

Against the shortcoming that the traditional method of fractal image compression coding has inferior decoding quality on the original image subject to salt-and-pepper noise interference, this paper raises a least absolute deviation (LAD) method to be applied in fractal image compression, which can replace the method of least square error in computing contrast and brightness adjustment value and solve the L1-norm recursive problem using weighted median. The experimental result indicates that the LAD method has a very good anti-noise effect on the outliers introduced by salt-and-pepper noise.

Keywords: Fractal Image Compression, Least Square Error Method, Least Absolute Deviation Method, Salt-and-Pepper Noise

1 Introduction

Put forward by Mandelbrot in 1975 [1], the fractal theory was first applied in image compression by Barnsley in 1988 [2]. It was not until Jacquin raised iterated function system (IFS) and local iterated function system (LIFS) [3] that the theoretical foundation of fractal image compression technique has been laid. Afterwards, this theory was used in image retrieval [4], digital watermarking [5], image inpainting [6] and image denoising [7], etc., respectively. The algorithm raised by Jacquin is based on the concept of local self-similarity of image, in which the local blocks can identify another similar block through three adjustment methods - contrast, brightness and reversal. The LIFS can automatically convert images into affine transform coefficients, which can achieve the aim of compression only by being stored up. Fractal image compression enjoys advantages like high compression ratio, irrelevance of resolution ratio, fast decoding and more, whereas the disadvantage is the overlong compressing hour as result of using the global searching method to seek for the optimal matching blocks. Therefore, in order to speed up the encoding and strengthen the image detail compensation, some scholars combine fractal with other algorithms. He Jia, zheng-kai liu [8] used low frequency coefficients in DCT as the matching feature, and made matching more rapid and accurate.

The LAD method was put forward by Boscovich in 1757, namely the L1-norm, whose aim is to minimize the absolute deviation through estimative parameters, though the weakness of non-differentiability left it unused for complicated computation. Many parallel methods, such as the Barrodale-Roberts [9] Algorithm, the Bartels-Conn-Sinclair Algorithm and the Maximum Likelihood Estimation Algorithm [10] did not rise until Edgeworth put forward resolving the problem of non-differentiability using weighted medians [11] in 1887 and Harris solved the LAD method using the simple concept of linear programming in 1950 [12].

In traditional fractal image compression algorithms, the least square error (LSE) method is adopted to determine brightness and contrast adjustment coefficients by contrasting the range blocks to the domain blocks. It can be known from the recursive principle that the LSE method is of no robustness, so the restored image has inferior quality upon being interfered by noise after undergoing compression. Replacing the traditional LSE method with the LAD method, we take the advantage of robustness with the LAD method to remove noise from the fractal images straightforward during the compression procedure without undergoing the pre-processing prior to noise-removal so that the quality of image is not affected by noise.

2 Theory evidence

2.1 LEAST SQUARE ERROR (LSE) METHOD

Fractal encoding performs compressed encoding by exploiting the characteristic of image's local self-similarity. Each block within an image may correspond to a big similar block. Taking the two groups of blocks in Figure 1 as an example, one group is the hat edge in correspondence to the hat in the mirror, the other being the similar but larger block in correspondence to the part of shoulder. The larger block approximates the smaller counterpart within the same group after being minimized and adjusted in contrast and brightness.

* ***Corresponding author*** e-mail: 13066724@qq.com

A 256-by-256 image can fall into non-overlapped n-by-n range blocks, the set of which is a range pool. Then the original image is divided into 2n-by-2n domain blocks that can be overlapped, the set of which is called a domain pool. The procedure of fractal image compression is to pinpoint the most similar domain block from the domain pool for each range block in the range pool. This procedure can be viewed as finding a domain block through convergent operations of affine transform.

FIGURE 1 Local Self-similarity of Fractal Image Compression

In the contrasting procedure, the square error is used to estimate the difference between the range block v and the domain block u after the sub-sampling. Smaller is indicative of higher similarity between the domain block u and the range block v, as shown in Equation (1).

$$E_k = \left\| (p_k u_k + q_k) - v \right\|^2, \; k=0,1,...,7, \tag{1}$$

where k denotes 8 directions of reversal; E_k, p_k, u_k and q_k represent the square error value, the contrast adjustment value, the block after the secondary sampling, and the brightness adjustment value, respectively, of the difference degree of the estimative block under the k^{th} reversal. $\hat{p}_k$ and $\hat{q}_k$ are the predicted values of p_k and q_k, respectively, which can derive from Equation(1)through partial differential. This method to compute p and q is just the LSE method, N in the following Equation being the size of the range block.

$$\hat{p}_k = \frac{N^2 < u_k, v > -(\sum_{j=0}^{N-1}\sum_{i=0}^{N-1} u_k(i,j)) \cdot (\sum_{j=0}^{N-1}\sum_{i=0}^{N-1} v(i,j))}{N^2 < u_k, u_k > -(\sum_{j=0}^{N-1}\sum_{i=0}^{N-1} u_k(i,j))^2}, \tag{2}$$

$$\hat{q}_k = \frac{1}{N^2}(\sum_{j=0}^{N-1}\sum_{i=0}^{N-1} v(i,j) - \hat{p}_k \sum_{j=0}^{N-1}\sum_{i=0}^{N-1} u_k(i,j)). \tag{3}$$

LAD Method

The LAD method is interpreted against the concept of linear regression, a model of which is assumed as Equation (4).

$$y_i = ax_i + b + \varepsilon_i, \; i=1.....L, \tag{4}$$

where x is the input value, y is the output value, and ε is the error term. When ε_i meets the following assumptions:

(a) $E(\varepsilon_i) = 0$;

(b) The variance number is constant;

(c) ε_i is a Gaussian distribution function whose formula of Gaussian distribution follows Equation(5), where the mean μ = 0 and the variance is σ;

(d) Each follows independent distribution.

When ε_i meets the above assumption, it is the optimal choice to solve Equation (4) using the LS method. When ε_i is assumed as a Laplace distribution function whose formula of Laplace distribution follows Equation (6) where the mean μ = 0 and the variance $\sigma = \frac{\sqrt{2}}{\lambda}$, and when ε_i meets the above assumptions (a), (b) and (d) with a Laplace distribution, it is the optimal choice to solve Equation (4) using the LAD method. Different methods are employed for the optimal solution according to different assumptions of ε_i.

$$g(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp(-\frac{(x)^2}{2\sigma^2}), -\infty < x < \infty, \tag{5}$$

$$f(x) = \frac{\lambda}{2} \exp(-\lambda|x|), -\infty < x < \infty, \tag{6}$$

The LAD method and the traditional LSE method are applied to Equation 4 respectively to produce Equation (7) and Equation (8).

$$E = \sum_{i=1}^{L} |y_i - (ax_i + b)| = \sum_{i=1}^{L} \mathrm{sgn}(e_i) \cdot e_i, \tag{7}$$

$$E = \sum_{i=1}^{L} (y_i - (ax_i + b))^2 = \sum_{i=1}^{L} e_i \cdot e_i. \tag{8}$$

In the above Equations, E is the sum of the parameters in group L, e_i is the error value of the parameters in the i[th] group. For the same group of parameters, e_i has identical value. Between both methods mentioned above, the difference lies in the fact that the LAD method takes the absolute value of e_i. When e_i is positive sgn (e_i) becomes 1, when e_i is negative sgn (e_i) becomes -1. While in the LSE method, the error value E will become greater after the value of e_i is squared. Under the circumstance where the LAD method is used, there is no significant difference with e_i between the interval [-1, 1] from the LSE method; but when outliers emerge to the data, e_i will be magnified at a square rate when the LSE method is employed, which leads the error E to become too great to make good judgment and estimation, so the value of e_i shall be kept from being magnified fast to reduce the effect of a few outliers on all the data, which is the robustness in inhibiting outliers, as shown in Figure 2.

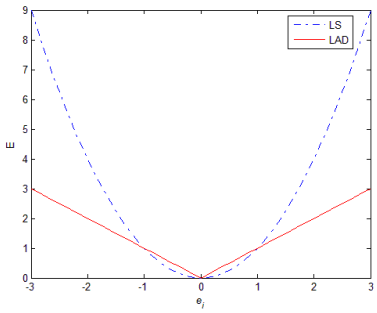

FIGURE 2 Relations between LAD, LSE and error E

2.2 MAXIMUM LIKELIHOOD ESTIMATES (MLE)

The LAD method cannot perform differential since absolute value exists, so the parameters with least absolute deviation value need to be determined through other methods. What is adopted in this paper is the maximum likelihood estimation algorithm [10], in which the weighted medians are operated. The weighted median starts from the viewpoint of geometric slope. Where the slope is greater than 0, the deviation value is minimum. It can be inferred as follows that the slopes after being sorted are on a progressive increase, turning from negative to positive as increasing to a certain value, which is the approximate minimum rising when the least deviation method is used. The proof goes as below:

$$F(a) := \sum_{i=1}^{L} |y_i - b - ax_i| = \sum_{i=1}^{L} |x| \left| \frac{y_i - b}{x_i} - a \right| = \sum_{i \in I\_(a)} |x_i| (a - \frac{y_i - b}{x_i}) + \sum_{i \in I_+(a)} |x_i| (\frac{y_i - b}{x_i} - a) \quad (9)$$

F(a) is the absolute value taken from Equation (4); *x* and *y* are the input and output, respectively, each holding the parameters in *L* Group, where:

$$I\_(a) := \left\{ i \in \{1.....L\} : \frac{y_i - b}{x_i} \le a \right\}$$

$$I_+(a) := \left\{ i \in \{1.....L\} : \frac{y_i - b}{x_i} > a \right\}$$

I_(a) is a set of parameters in *L* Group whose slopes are smaller than *a*; $I_+(a)$ is a set of parameters in *L* Group whose slopes are greater than *a*. Partial differential is applied to *a* in Equation (9) to get the slope as Equation (10). The minimum deviation value is determined by the LSE method when the slopes are 0. Since the LAD method is linear and continuous, it is taken that $F'(a) \ge 0$. While the parameter in correspondence to the slope turning from negative to positive reaches the minimum.

$$F'(a) := \sum_{i \in I\_(a)} |x_i| - \sum_{i \in I(a)_+} |x_i| \ge 0, \quad \sum_{i \in I\_(a)} |x_i| \ge \sum_{i \in I_+(a)} |x_i| \quad (10)$$

$$2 \sum_{i \in I\_(a)} |x_i| = \sum_{i \in I\_(a)} |x_i| + \sum_{i \in I\_(a)} |x_i| \ge \sum_{i \in I\_(a)} |x_i| + \sum_{i \in I_+(a)} |x_i| = \sum_{i=1}^{L} |x_i|$$

$$\sum_{i \in I\_(a)} |x_i| \ge \frac{1}{2} \sum_{i=1}^{L} |x_i| . \quad (11)$$

According to Equation (10), when 5 groups of parameters are input, the change of their slopes is shown as Figure3. The slopes are sorted as 1, 2, ..., 5 in an incremental order, whereas the slopes are $\frac{y_{[i]} - b}{x_{[i]}}$, and the corresponding parameters can be yielded. At Interval (3) $F'(a)$ is negative while becoming positive at Interval (4), so Interval (4) is the first group of data $x_{[4]}$ when $F'(a) \ge 0$. And Figure 3 indicates that the minimum should be among $x_{[3]}$. It can be known from Equation (11) that the input data are within the set of *I_(a)*. As the data $x_{[1]}$ input at the first time are accumulated to the data $x_{[i]}$ input at the ith time and when the accumulated sum is greater than one half of the sum of all input data, the input data at the ith time are the input ones of the first positive slope when the slope just turns from negative to positive. From Equation (11) it can be found the first datum where $F'(a) \ge 0$ is the one input at the ith time, so the minimum deviation value may occur when the datum is input at the (i - 1)th time.

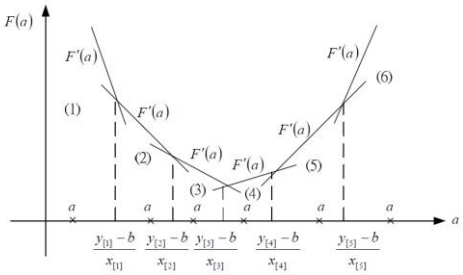

FIGURE 3 Conceptual Schematic Diagram of Weighted Median

Figure 3 reveals the minimum deviation value may occur among the data in the third group. It can be concluded from Equation (11) that, When the input data *L* group, the minimum deviation value may be among the data input at the (i - 1)th time. The weighted medians compute the slope of the data with the least deviation value. They are denoted by *MED*(•) as below:

$$a = MED(x_i \Diamond \frac{y_i - b}{x_i} |_{i=1}^{L}) . \quad (12)$$

The steps to compute the weighted medians are as follow:

Step I: Assume $w_i = \frac{y_i - b}{x_i}$, record the slope input each time.

Step II: Compute the threshold value $x' = (1/2)\sum_{i=1}^{L} x_i$.

Step III: Express all the slopes $w_1 ..... w_L$ as $w_{[1]} \le ..... \le w_{[L]}$ after sorting them; in correspondence to $w_{[i]}$ after being sorted, the relevant input data is $x_{[i]}$ as the weight.

Step IV: Apply summation to $x_{[i]}$ one after another; record the index value j that first meets $\sum_{i=1}^{j} x_{[i]} \ge x_0$, then the index value of the minimum is j - 1.

Step V: $w_{[j-1]}$ is the slope in correspondence to the minimum; the computation for the weighted medians is just done by letting $a = w_{[j-1]}$.

The above is introduction to the concept of and steps for weighted median, whereas the following provides illustration on how MLE figures out the slope and the gap by means of the weighted medians. In order to accelerate convergence after using the weighted medians, MLE transforms the space to finely adjust the slope, thereby to get more accurate slope, reduce the times of training, and get the slope with the least error and the corresponding gap through fast convergence.

The MLE calculation method 4 offers to pinpoint the parameters a and b in correspondence to the minimum E in Equation (7).

The steps are as follow:

Step I: Set the times of recursion as k = 0 at the very beginning; $b = b_k$ is yielded through calculation using the LSE method, as shown in Equation (13):

$$b_0 = \frac{\sum_{i=1}^{L}(x_i - \bar{x}) \times (\bar{y}x_i - \bar{x}y_i)}{\sum_{i=1}^{L}(x_i - \bar{x})^2}, \quad (13)$$

$$\bar{x} = (1/L) \times \sum_{i=1}^{L} x_i \ , \ \bar{y} = (1/L) \times \sum_{i=1}^{L} y_i$$

Step II: Compute the parameter a_0 using the weighted medians, expressed as Equation (14):

$$a_0 = MED(|x_i| \Diamond \frac{y_i - b_0}{x_i}) \Big|_{i=1}^{L}). \quad (14)$$

Determine the index value h for existence of least deviation value. The parameter a_0 can be yielded from Equation (14), accordingly update $a_{old} = a_0$.

Step III: Let $k = k + 1$ to convert the input spatial coordinate $z_i = x_i - x_h$.

Step IV: Compute $a'_{k-1} = a_{k-1}$, $b'_{k-1} = b_{k-1} + a_{k-1}x_h$ and the weighted median a'_k as Equation (15):

$$a'_k = MED(|z_i| \Diamond \frac{y_i - b'_k}{z_i}) \Big|_{i=1}^{L}). \quad (15)$$

Compute from Equation (15) the new index value m and the corresponding parameter a'_k.

Step V: Compute $a_k = a'_k$ and $b_k = b'_k - a'_k x_h$ by converting the original spatial coordinate.

Step VI: Let $h = m$. Stop where the variances of a_{old} and a_k are below the permitted value or where the time of recursion exceeds the set value; otherwise update $a_{old} = a_0$ and return to Step III. The above steps can be expressed by the flowchart as Figure 4.

3 Application of LAD in fractal image compression

The workflow of introduction of LAD in fractal image compression bears general similarity to traditional methods of fractal compression, the only difference being how to compute p and q and utilize the absolute deviation as an indicator of estimation, as shown in Figure 5.The main steps by which to replace LS with LAD are as follow:

Step I: Fall the original image into an 8-by-8 non-overlapped range block v and a 16-by-16 overlapped domain block u.

Step II: Apply secondary sampling to u and perform reversal at k.

Step III: The iteration time t = 0. Compute the initial $q_k = \hat{q}_k$

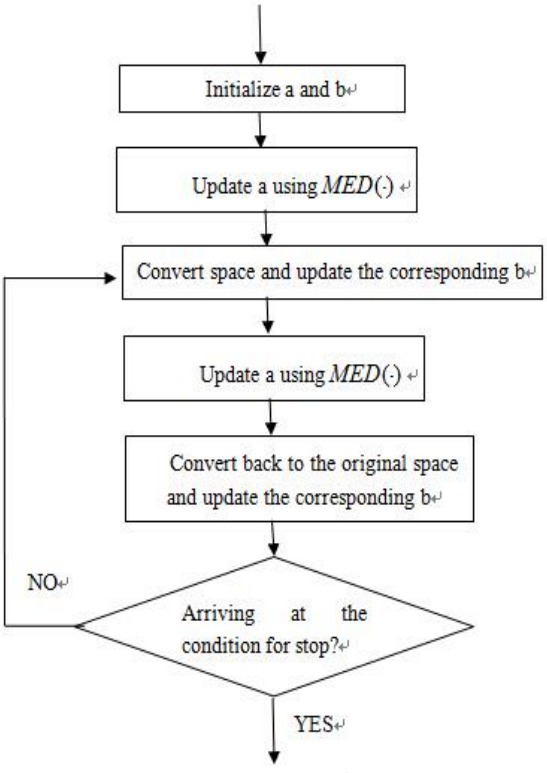

FIGURE 4 Flowchart of LAD

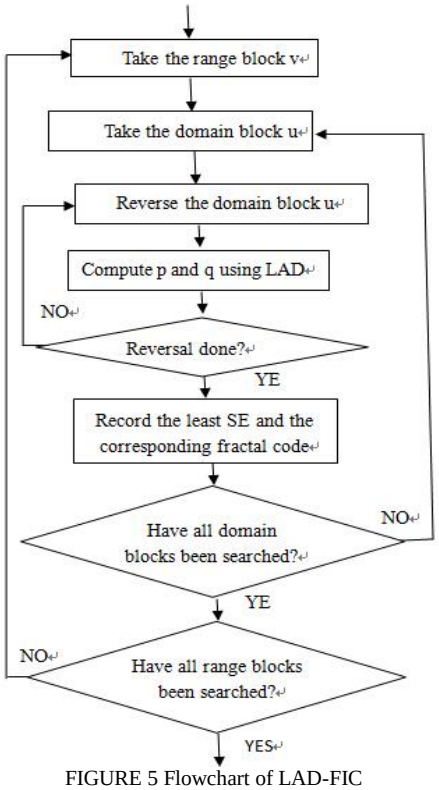

FIGURE 5 Flowchart of LAD-FIC

Step IV: Figure out pk using MED(•), expressed as Equation (16):

$$p_k = MED(|u_k(i,j)| \Diamond \frac{v(i,j)-q_k}{u_k(i,j)})\Big|_{i,j=0}^{N-1}), \qquad (16)$$

Where N is the size of the range block v. According to the above Equation, the least deviation value within the 8-by-8 $u_k(i, j)$ is $(h1, h2)$, whereby to update $p_{old} = p_k$.

Step V: Let $t = t + 1$. Convert the input space $z(i,j) = u_k(i,j) - u_k(h1,h2)$.

Step VI: $q_k = q_k + p_k u_k(h1,h2)$ and p_k after space conversion are shown as Equation (17):

$$p_k = MED(|z(i,j)| \Diamond \frac{y(i,j)-q_k}{z(i,j)}\Big|_{i,j=0}^{N-1}). \qquad (17)$$

According to the above Equation, the least deviation value within $z(i, j)$ is $(m1, m2)$.

Step VII: Convert to the original space, where $q_k = q_k + p_k u_k(h1,h2)$.

Step VIII: Let $h1 = m1$, $h2 = m2$. Stop where the variances of p_{old} and p_k are below the permitted value or where the time of iteration exceeds the set value; otherwise update $p_{old} = p_k$ and return to Step IV. LAD offers to compute p_k and q_k from Step IV through Step VIII.

Step IX: Return to Step II if none of the eight directions of reversal has been used.

Step X: Record the fractal code in correspondence to the least absolute deviation in Equation (15).

$\min(E_K = |(p_k u_k + q_k) - v|)$, $k=0,1,...7$

Step XI: Apply global search to the domain pool to pinpoint the domain block u in correspondence to each range block v. Thus the LAD-FIC computation is done.

4 Experimental result

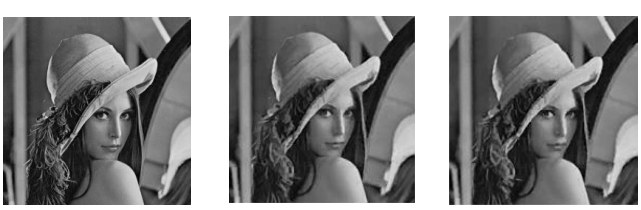
The tool for experiment in this paper is Visual C++ 6.0, the operating system is Microsoft Windows XP, the CPU is Intel Core i5 3450, and the internal memory is 4G. In this section, a comparison will be made between the traditional method of fractal compression and the LAD-introduced method of fractal image compression for multiple frames of images where different noises are included. The images in use are all 256-by-256, the size of range block being 8-by-8. The condition under which MLE stops is that the time of iteration reaches 5 or that the difference between the yielded p value and the previous p value is smaller than 0.05. PSNR, which is used to evaluate the quality of the decoded image, is defined as Equation (18), whereas MSE is defined as Equation (19).

$$PSNR(f, \hat{f}) := 10 \cdot \log_{10}\left(\frac{255^2}{MSE(f, \hat{f})}\right), \qquad (18)$$

$$MSE(f, \hat{f}) = \frac{1}{256^2} \cdot \sum_{i=1}^{256}\sum_{j=1}^{256}(f(i,j) - \hat{f}(i,j))^2, \qquad (19)$$

where f is the original image, $\hat{f}$ is the decoded image.

Initially, the Lena image in which no noise has been included offers as the image to test. The traditional fractal image compression (FIC) method and the fractal image compression method where LS gives way to LAD (LAD-FIC) are used separately to observe the effects of compression by both, as shown in Figure 6. Baboon is the initial image to decode. Through 9 times of iteration, Figure 6(b) is the image decoded by FIC, whose PSNR value is 28.86dB. Figure 6(c) is the image decoded by LAD-FIC, whose PSNR value is 28.27dB. The images decoded by both methods have almost the same PSNR, wherefrom both LAD-FIC and FIC methods can be verified to make the same effect in terms of compression.



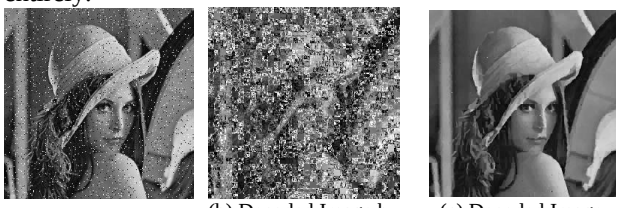
(a) Original Image Lena

(b) Decoded Image by FIC, PSNR = 28.86dB

(c) Decoded Image by LAD-FIC, PSNR = 28.27dB

FIGURE 6 Contrasted Effects of Lena Image Tested by FIC and LAD-FIC

Next, it is attempted to include 5% and 10% salt-and-pepper noises in the four images (Lena, Baboon, Pepper and F16). After being compressed by both methods, all the decoded images are based on Baboon as the initial image but Baboon itself, which is based on Lena as the initial image. The decoded images are produced after 9 times of iteration. Figure 7(a) is the image by including the 5% salt-and-pepper noise in Lena. Figure 7(b) and Figure 7(c) are the decoded images after FIC and LAD-FIC are used for compression. Obviously, it can be seen that Figure 7(b) has been vulnerable to noise in that its decoded image fails to restore Lena but presents only a few lines across big blocks which cannot clearly distinguish the original image. The difference between the PSNR values of Figure 7(c) and Figure 6(c) is only 1dB, wherefrom it can be seen that LAD-FIC can almost remove the effect of the 5% salt-and-pepper noise entirely.



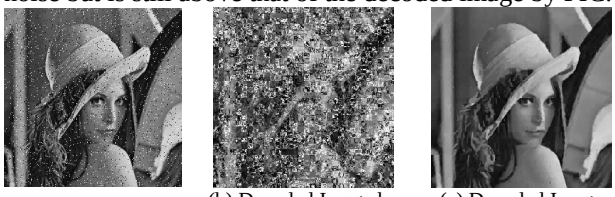
(a) 5% Salt-and-Pepper Noise

(b) Decoded Image by FIC, PSNR = 11.87dB

(c) Decoded Image by LAD-FIC, PSNR = 27.21dB

FIGURE 7 Lena Image for Testing 5% Salt-and-Pepper Noise

Next, 10% salt-and-pepper noise is then included in the test. Figure 8(a) is the image by including the 10% salt-and-pepper noise in Lena. Figure 8(b) is the decoded image by FIC whose PSNR value is 11.41dB, with only a bit more inferior effect than 7(b) though the quality of image has been so poor as to obscure the original image. Figure 8(c) is the decoded image by LAD-FIC whose PSNR value is 26.42dB, which falls below the counterpart of Figure 7(c) for the image's vulnerability to noise but is still above that of the decoded image by FIC.



(a) 10% Salt-and-Pepper

(b) Decoded Image by FIC, PSNR = 11.41dB

(c) Decoded Image by LAD-FIC, PSNR = 26.42dB

FIGURE 8 Lena Image for Testing 10% Salt-and-Pepper Noise

The test is conducted on the three other images by the same method. To illustrate it with Table 1, the parameter *S* in the table denotes the salt-and-pepper noise. The experiment demonstrates that the PSNR value of the decoded image produced through fractal compression on the image in which the salt-and-pepper noise has been included has decline to a considerable degree, whereas LAD-FIC remains not affected by this noise, therefore LAD-FIC has the effect of resisting the salt-and-pepper noise

TABLE 1 the PSNR (unit: dB) Values of Pepper, Baboon and F16 under 5%, 10% and 20% Salt-and-Pepper Noises

	Pepper		**Baboon**		**F16**	
	FIC	*LAD-FIC*	*FIC*	*LAD-FIC*	*FIC*	*LAD-FIC*
Original Image	29.78	29.31	20.03	19.82	25.17	24.43
S=5%	17.89	27.88	15.43	19.26	12.83	23.71
S=10%	17.96	27.21	17.56	20.12	5.53	23.23
S=20%	18.31	25.92	17.41	18.33	6.24	22.67

5 Conclusion

Traditional techniques of fractal image compression fail to discuss how to resist noise, so the quality of compression will be vulnerable to noise when the original image is interfered by noise. The LAD method of robustness used in substitution for the traditional LSE method endows the image with the capacity of resisting the salt-and-pepper noise, namely the LAD-FIC solution proposed in this paper can remove noise while compressing the image. This method makes extremely excellent effect on images vulnerable to the salt-and-pepper noise, yet there is no distinct effect for Gaussian noise and Laplace noise. Since LAD-FIC first uses FIC to estimate the rough contrast and brightness adjustment value prior to further adjustment to figure out the accurate contrast and brightness adjustment value, it is discovered through a comparison between both that the time cost for LAD-FIC is 18 times that for FIC. In the research direction in the future, it is hoped that the compressing time can be further reduced, or the contrast and brightness adjustment value can be changed to get their linear relationship, on the premise of guaranteeing its robustness, so as to achieve a higher quality of compression.

Abstract

Firstly, this paper pre-processes the image to be segmented through grey-scale morphological method. Then, based on the in-depth analysis of basic ant colony algorithm, it explains the shortcomings of this algorithm; proposes the improved strategy of ant colony algorithm, namely fuzzy ant colony algorithm, which designs the fitness function of artificial ant colony algorithm with minimum cross entropy and applies the improved fuzzy ant colony algorithm in the spatial-domain noisy image single segmentation. Finally, starting from the segmentation results and convergence, it compares the performances of the improved ant colony algorithm and the basic ant colony algorithm, GA algorithm and AFS algorithm.

Keywords: Noisy Image, Ant Colony Algorithm, Histogram Feature, Threshold Segmentation, Cross Entropy

1 Introduction

This paper is aimed to study the swarm intelligent optimization algorithm based on ant foraging behaviour, namely the artificial ant colony algorithm. The early ant colony algorithm is mostly used in solving function optimization problems. For example, some scholars see the honey of the artificial ant colony algorithm as the possible solution of the function and achieve satisfactory results in optimizing function with ant colony algorithm. Other scholars consider the objective function in the engineering as virtual food and settle the optimization problems of two-dimensional functions with virtual ant colony algorithm. Later, starting from the optimization problems of high-dimensional functions, some scholars demonstrate the excellent performances of artificial ant colony algorithm by comparing particle swarm optimization and other algorithms before they use ant colony algorithm to solve the data clustering problems.

As a new swarm intelligent model, ant colony algorithm still encounters the following problems used in image segmentation. 1)The initialized population is randomly generated in the solution space without considering the characteristics of the image to be segmented; 2)In the threshold search of the basic ant colony algorithm, the individual movement in the population can be seen as a random process in a certain range; however, the actual individual movement has certain fuzziness[1].

Based on the above analysis, this paper improves the optimization efficiency of the intelligent model by integrating the histogram information of image to be segmented, the fuzzy theory and the artificial ant colony algorithm. On the basis of the improved ant colony algorithm, the design of noisy image segmentation is intended to analyse the characteristics of the image to be segmented and suppress the image noise through open operation and closed operation in the grey-scale morphology. Then design the fitness function of the artificial ant colony algorithm with the minimum cross entropy and narrow down the threshold search range of the ant colony by using the histogram information of the image in order to guarantee the image segmentation speed; consider the ant movement process as the fuzziness process and conduct fuzzy control with fuzzy theory. Finally, quickly find the optimal threshold with the improved artificial ant colony algorithm [2].

2 The proposed algorithm

With the advancement in networking and multimedia technologies enables the distribution and sharing of multimedia content widely. In the meantime, piracy becomes increasingly rampant as the customers can easily duplicate and redistribute the received multimedia content to a large audience.

2.1 THE IMAGE PRE-PROCESSING OF THE HISTOGRAM ANALYSIS BASED ON GREY-SCALE MORPHOLOGY

It is indicated in the documents that the grey-scale morphological pre-processing can effectively suppress the speckle noise in the noisy images. Therefore, in the noisy image segmentation, we first pre-process the image to be segmented with grey-scale morphology to reduce the noise in the image and then narrow down the

[*] ***Corresponding author*** e-mail: 153569367@qq.com

threshold distribution range according to the grey-scale histogram of the pre-processed image.

Take Fig.1 as example. Fig. 1(a) is the original noisy image and Fig.1(b) is the grey-scale histogram after pre-processing (a) with grey-scale morphology. Assume the possible threshold of the image is T, there are obvious differences in the grey scale between the segmentation target and the background, namely that there are two obvious twin peaks in the histogram of the pre-processing image. The threshold is located in the bottom of the twin peaks and its distribution range is between the twin peaks, namely $T \in [m,n]$ in Fig. 1(b).

The solving method of m and n is to calculate the average grey scale of the image in the histogram. Missing the grey scale among [0, c] with the biggest possibility and n is the grey scale among [c+1, 255] with the biggest possibility.

3 The fuzzy ant colony algorithm

3.1 THE PROBLEMS IN ANT COLONY ALGORITHM

There are still some problems when ant colony algorithm, a new swarm intelligent model is used in image segmentation, including:

1) The initialized population is generated in the solution space without considering the characteristics of the image to be segmented;

2) In the threshold search process of the basic ant colony algorithm, the individual movement in the colony can be seen as a random process in a certain range while the actual movement has certain fuzziness [3].

3.2 FUZZY CONTROL THEORY AND FUZZY MEMBERSHIP FUNCTION

Fuzzy control theory has been used increasingly extensive because no precise mathematical model of the controlled object is needed to be built when designing system. The existing Methods determine fuzzy membership function include:

1) Fuzzy statistical method: make a clear judgment whether a determined element belongs to a variable clear collection in the domain of discourse;

2) Exemplification: estimate the membership function of the fuzzy subset according to membership frequency of limited fuzzy subsets;

3) Expert experience method: determine the membership function according to the processing equation or the corresponding weight coefficient of the fuzzy information given by the actual expert experience;

4) Binary comparison ordering method: determine the general shape and order under certain characteristics through the paired comparisons of multiply objects so as to determine the membership function of the characteristics and these objects [4].

The reconnaissance ant in the basic ant colony algorithm generates a new position randomly in the search space to improve food source. Such new position is so uncertain that it can be seen as a fuzzy process.

In the below text, we determine the fuzzy membership function by using the exemplification in the fuzzy control so as to control the search range of the reconnaissance ant in the artificial ant colony algorithm. After repeated experimental observation, the ant colony has better optimization effects to fulfil this process according to Formula (1) and Formula (2) is the fuzzy control factor.

$$v_{ij} = x_{ij} + \varphi \times (\omega, \theta, t) \times x_{ij}, \quad (1)$$

$$\mu(\omega, \theta, t) = 1/[1 + \exp(-\omega t - \theta)]. \quad (2)$$

In the above formula, v_{ij} is a new possible solution generated by the ant; x_{ij} is the ant which needs improvements; i is the i^{th} ant; j is the number of dimension of the solution space; φ is a random number among [-1,1]; $\mu(\omega, \theta, t)$ is the fuzzy membership function and ω and θ are a set of values from the experiments. In this paper, $\omega = -0.2$, $\theta = 2$ and t is the current iterations [5, 6].

According to Formula (1), with the increase of iterations, the search range of the ant is self-adaptive to the changes. To be specific, in the initial search, the ant is far from the optimal solution and the search range is big, guaranteeing the diversity of the individuals in the colony ad in the later search, the ant is closed to the optimal solution and its search range is small, avoiding oversized step size and skipping the optimal solution [7].

4 The spatial-domain noisy image single threshold segmentation based on fuzzy colony algorithm

The general noisy image has some speckle noise due to other interferences. Therefore, effectively suppress the noise interference before segmenting the image and get the precise segmentation image. This paper pre-processes the image to be segmented with grey-scale morphology and reduce the noise interference. Then, it narrows down the search range of the threshold with the pre-processed image histogram and enhances the optimization speed. On this basis, it takes the two-dimensional cross entropy as the fitness function of the ant colony algorithm and finds the optimal segmentation threshold of the image through fuzzy ant colony algorithm.

In conclusion, the spatial-domain noisy image segmentation process based on fuzzy ant colony algorithm is classified as follows.

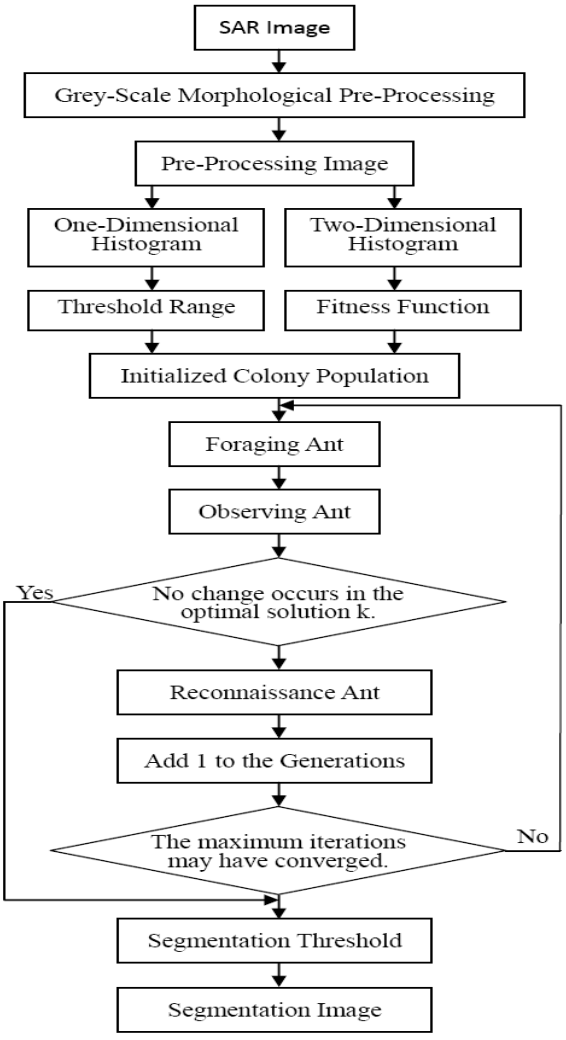

FIGURE 2 The spatial-domain noisy image segmentation based on fuzzy ant colony algorithm

The main steps are as follows:

(1) Pre-process the image to be segmented with appropriate grey-scale morphological factor and get the enhanced image;

(2) According to the histogram feature of the denoised image, narrow down the search range of the threshold to $[m,n]$, namely min and max in the artificial ant colony algorithm are m and n respectively;

(3) According to the grey scale and neighbourhood grey-scale information of the denoised image, get the grey-scale-neighbourhood-grey-scale histogram and calculate the minimum cross entropy in the image:

$$D(s,t)=\sum_{i=m}^{s}\sum_{j=m}^{t}\left[ijp_{ij}\ln\frac{ij}{\mu_1(s,t)}+\mu_1(s,t)p_{ij}\ln\frac{\mu_1(s,t)}{ij}\right]+\sum_{i=s+1}^{n}\sum_{j=t+1}^{n}\left[ijp_{ij}\ln\frac{ij}{\mu_2(s,t)}+\mu_2(s,t)p_{ij}\ln\frac{\mu_2(s,t)}{ij}\right] \quad (3)$$

In the formula, $P_1=\sum_{i=m}^{s}\sum_{j=m}^{t}p_{ij}$, $P_2=\sum_{i=s+1}^{n}\sum_{j=t+1}^{n}p_{ij}$, $\mu_1(s,t)=\frac{1}{P_1}\sum_{i=m}^{s}\sum_{j=m}^{t}ijp_{ij}$, $\mu_2(s,t)=\frac{1}{P_2}\sum_{i=s+1}^{n}\sum_{j=t+1}^{n}ijp_{ij}$, s is the grey-scale value; t is the average neighbourhood grey-scale value and p_{ij} is the grey-scale-neighbourhood-grey-scale joint probability;

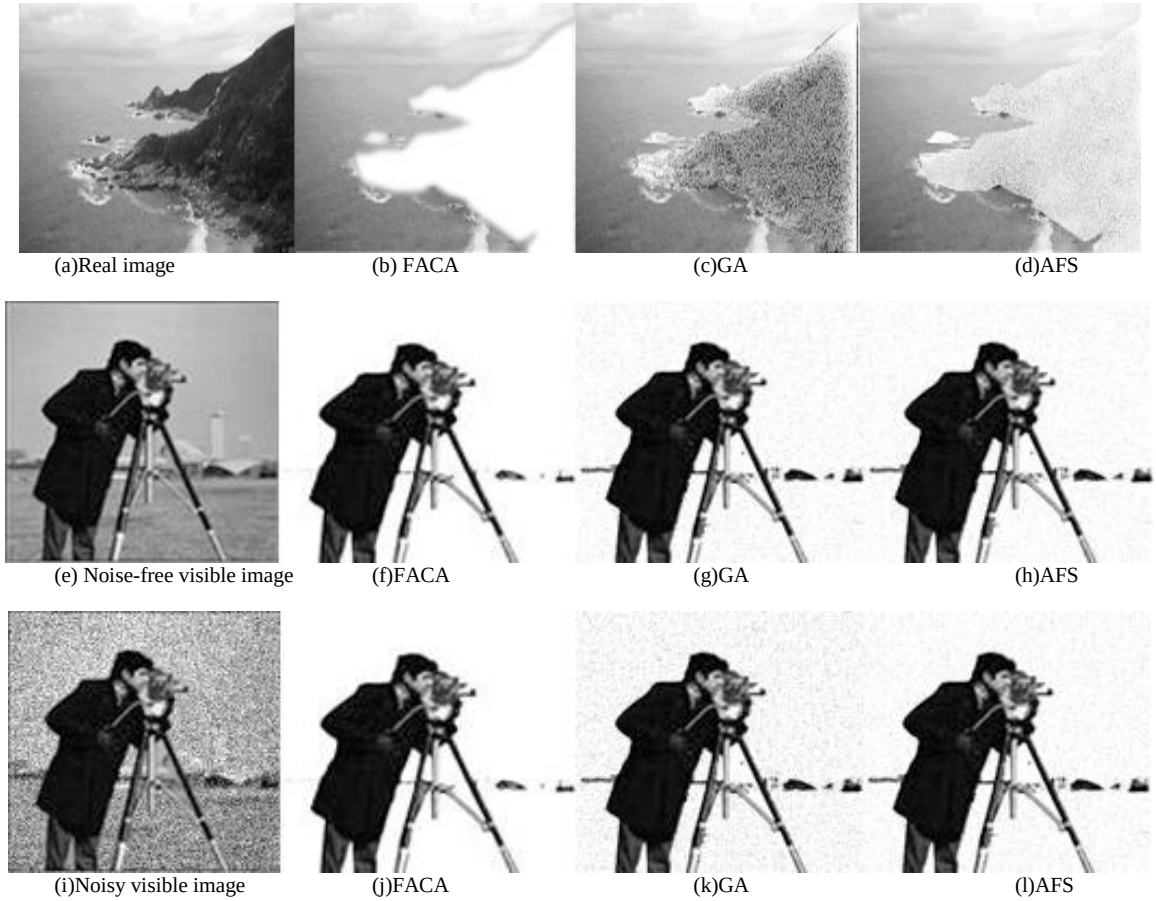
(4) Choose the reciprocal of Formula (3) as the fitness function of the artificial ant colony algorithm and then the corresponding (s,t) is the optimal threshold when the value of $\frac{1}{D(s,t)}$ is maximum;

(5) Segment the image according to the threshold (s,t) and the specific operation is as follows. If the sum of the grey scale of the pixel point (x,y) and the average neighbourhood grey scale is among $[0,s+t]$, then this point is the target pixel with a grey-scale value of 0; otherwise, this point is a background pixel with a grey-scale value of 1 [8].

5 Experimental results and analysis

5.1 THE COMPARISON OF SEGMENTATION RESULTS

The following are a group of image segmentation results by fuzzy ant colony algorithm, GA algorithm and AFS algorithm with visible image, noisy visible image and real image. Results are indicated as Fig. 3.



(a)Real image (b) FACA (c)GA (d)AFS

(e) Noise-free visible image (f)FACA (g)GA (h)AFS

(i)Noisy visible image (j)FACA (k)GA (l)AFS

FIGURE 3. The comparison of the image segmentation results by different optimization algorithms

From Fig.3, it is clear that no target regions has been split when segmenting the real noisy image; the noise has been split completely and there is a hole in the target when segmenting the noise-free visible image and the target has been split precisely when segmenting the noisy visible image since it is sensitive to the noise. Only part of target region has been split when segmenting the real noisy image; a hole appears in the target when segmenting the visible image and the noise and the target haven't been split well when segmenting the noisy visible image. The segmentation method based on fuzzy ant colony algorithm has strong noise immunity and get an intact and clear segmentation image target on the real noisy image with serious speckle noise, the visible image and the visible image with speckle noise.

5.2 THE COMPARISON OF ALGORITHM CONVERGENCE

In order to verify the quick optimization of fuzzy ant colony algorithm, the paper compares its convergence with the basic ant colony algorithm, the genetic algorithm and the artificial fish swarm algorithm with fixed experimental parameters. Make the individuals of the population in the fuzzy ant colony algorithm, the basic ant colony algorithm, GA algorithm and AFS algorithm as 20 and the population search times as 30. Compare the convergence of the fitness function curve when comparing the above algorithms in segmenting Fig. 3(a), as indicated in Fig. 4.

From Fig. 4, it can be seen that the fuzzy ant colony algorithm has converged in the 5th generation and it can search the optimal segmentation threshold; the basic artificial ant colony algorithm has converged in the 13th generation; the genetic algorithm hasn't converged in the 30th generation, so it can't find the optimal threshold and the artificial fish swarm algorithm has converged in the 19th generation, but it hasn't excellent stability. Therefore, the fuzzy ant colony algorithm can converge stably and quickly with small population and search times.

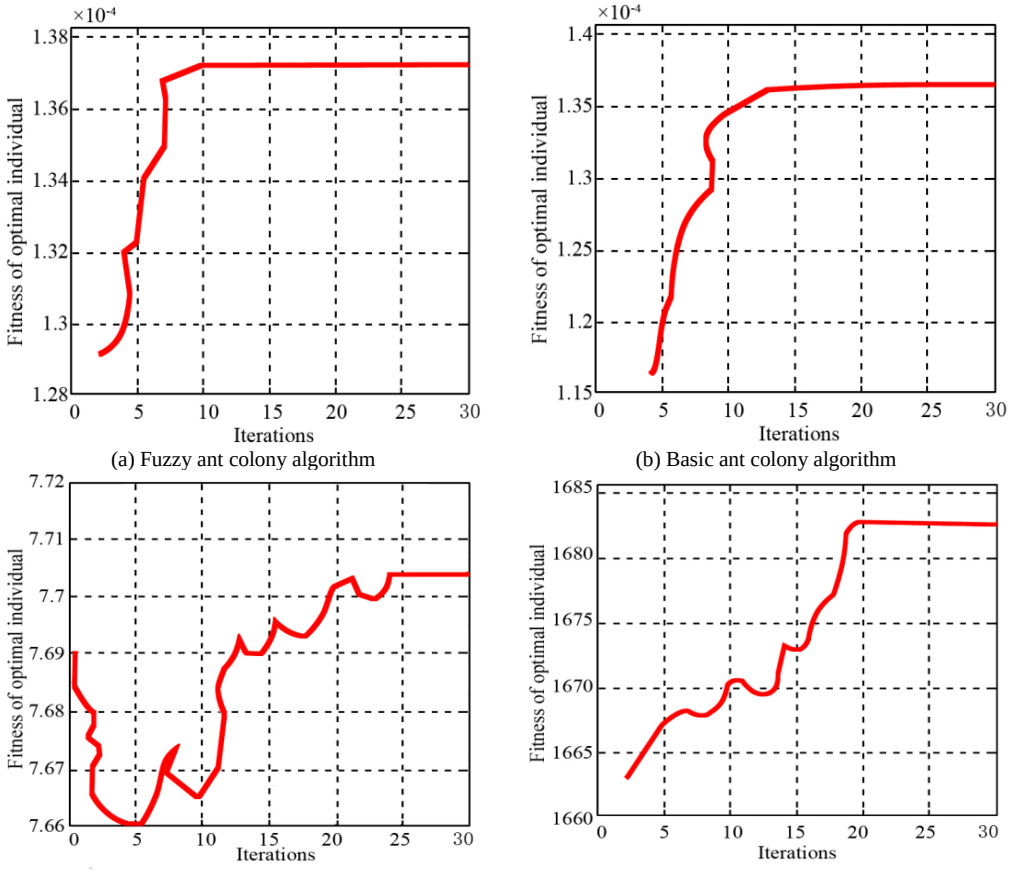


FIGURE 4 The convergence curve of the optimal

6 Conclusion

This paper has come up with a new spatial-domain noisy image segmentation method based on fuzzy ant colony algorithm. The main characteristic of this method is to make full use of the grey-scale features of the image to be segmented. It reduces the noise interference in the noise image segmentation through the grey-scale morphological pre-processing and effectively narrows down the threshold search range by pre-processing the histogram information of the image, which is good for the swarm intelligent algorithm to converge in a shorter time and guarantees the quickness of the segmentation speed. In improving the basic ant colony algorithm, it determines the search range of the reconnaissance ant via the fuzzy control dynamics and accelerates the convergence speed of the ant colony algorithm. The experimental results show that the method in this paper is better than the image segmentation methods based on the genetic algorithm and the artificial fish swarm algorithm in the noise immunity, precision, quickness and stability. The thing to note here is that this method is applicable for the image presenting twin-peak shape after grey-scale morphological processing and further exploration is needed to the images with mixed target and background noise.

Abstract

As many other inverse problems, human face image super-resolution is an ill-posed problem. The problem has been approached in the context of example-based superresolution learning. However, these methods need to run though all the sample set, which results in high calculation load and image degradation because of mis-matching. In this paper, we propose a new face image superresolution algorithm based on Support Vector Regression (SVR) pre-classified learning. A Principal Component Analysis (PCA) based pre-process is used to select a subset of samples. Then the best-matching sample images are trained to ensure the content relevance between the sample patch and the input low-resolution image. Further improvement involves a combination of classification and SVR-based techniques. Therefore, experiment results show that the proposed algorithm gets better reconstruction performance and faster program running speed.

Keywords: Face Super-resolution, Support Vector Machine (SVM), Principal Component Analysis (PCA), Example-based Algorithm

1 Introduction

The super-resolution reconstruction is the technology of using software algorithms to obtain higher resolution images without changing current imaging system hardware, which has been an active research in image processing and is widely applied in medical diagnosis, remote sensing and many other areas. Among them, face image has been specially focused in the field of image processing and pattern recognition. The traditional face super-resolution algorithms usually accord to the multiframe low-resolution (LR) images of sub-pixel displacement under same scenes to reconstruct high-resolution (HR) images. The single frame face image super-resolution algorithm based on training set reconstructs the high-frequency details of images by learning the relation between HR and LR images, which has become the mainstream of research area in recent years [1-5].

Human face super-resolution algorithm was first proposed by the Carnegie Mellon University's Simon Baker [6] etc., which builds a Gauss Pyramid with multi-resolution feature of HR images. By matching in different resolution spaces in the Pyramid and using the feature of images, the algorithm searches the corresponding HR patch from the side of matching the input image's feature. Framework of Bayesian inference is used to build the generating optimized model of HR images, then reconstructs the HR face images. This algorithm gets better reconstruction result than interpolation and traditional methods based on the Markov Network model. However, it is necessary to set up a huge sample database where we can do the traversal search, which leads to a heavy workload of calculating and the mismatching in search result will cause final quality decrease badly. Furthermore, the algorithm doing super-resolution reconstruction relies on its Gauss Pyramid model from the model of matched feature. It is limited for the improved room of subjective reconstructed quality when there is aliasing in sample feature extracting.

In this paper, we propose a face super-resolution algorithm based on SVM-improved learning. To solve the problems based on learning-based algorithm such as the heavy work of calculating and mismatching, we use a classifier to pre-classify the sample database and select the subset that is similar to the object's PCA feature, which reduces the mismatching rate of sample patch, shortens the program's running time and improves the image reconstruct performance.

2 SVM learning

SVM is on the base of Vapnik-Chervonenkis (VC) Dimension theory and Structural Risk Minimization (SRM) principle, to get better generalization ability according to limited sample details to find a best way to balance between the complexity of model and learning ability [7]. The main idea of SVM is to build a linear hyperplane as the decision boundary to make the margin

* ***Corresponding author*** e-mail: tangjl@jsut.edu.cn

between positive example and negative example maximum. Please see Figure 1.

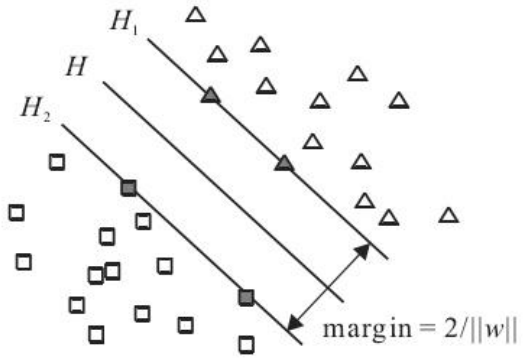

FIGURE 1 Schematic diagram of SVM learning.

More exactly to speak, SVM is a kind of generalized linear classifier based on SRM principle whose basic strategy is to confirm the empirical risk and to make confidence risk minimum.

The general type of classification hyperplane can be written as $wx+b=0$, after normalizated, which makes the linear separable sample set $(x_i, y_i), x_i \in R^d, y_i \in \{+1,-1\}, i=1,2,\cdots,n,$ meeting the following requirement:

$$y_i\left(wx_i+b\right)\geq 1, i=1,2,\cdots,n\ . \tag{1}$$

When margin is equal to $2/\|w\|$, so it is equal between maximizes margin and minimizes $\|w\|^2$. A hyperplane, which fits the condition (1) and makes $1/2\|w\|^2$ minimum is named optimal classification hyperplane, the training sample set is called support vectors, which makes the equal sign exist. Bring in the Lagrange function:

$$L=\frac{1}{2}\|w\|^2-\sum_{i=1}^{l}a_i y_i(w\cdot x_i+b)+\sum_{i-1}^{l}a_i\ . \tag{2}$$

Among in Equation (2), $a_i>0$ is the coefficient of Lagrange. Transform the question about optimal classification hyperplane into its dual problem by Lagrange optimization method, namely means becoming the question under the constraint of the inequality to search the best answering whose answer is unique solution. The optimal classification function is:

$$f(x)=\operatorname{sgn}\left\{\left(w^*x\right)+b^*\right\}=\operatorname{sgn}\left\{\sum_{i=1}^{n}\alpha_i^* y_i(x_i x)+b^*\right\}. \tag{3}$$

Among Equation (3), α_i^* is the corresponding Lagrange multiplier of each sample, we can prove only a few α_i^* is non-zero, then the corresponding sample is support vector. b^* is the classification threshold, which can acquire by any support vector or averaging from any couple of support vector.

For the sample set linearly non-separable case, we can put a slack variable $\delta_i\geq 0$, it becomes:

$$y_i\left(wx_i+b\right)\geq 1-\delta_i, i=1,2,\cdots,n\ . \tag{4}$$

And change the target into:

$$\min_{w,b,\delta}\varphi(w,x)=\frac{1}{2}w^T w+C\sum_{i=1}^{n}\delta_i\ . \tag{5}$$

To get the generalized optimal classification hyperplane by building a soft margin that considering in half way between minimum mistakes sub-sample and maximum margin, $C>0$ is a constant, which controls the level of punishment for the wrong sub-sample.

For the non-linear case, we can change it into a high-dimensional linear problem by non-linear variation. Generally speaking, this kind of non-linear variation is more complex, and hardly come true through the algorithm. We can use kernel function $K(x_i, x_j)$ who meets the Mercer's condition instead of original space's inner product, which will realize the linear classification after some non-linear variation, so that will avoid the concrete form of non-linear variation. The classification function is becoming:

$$f(x)=\operatorname{sgn}\left(\sum_{i=1}^{n}\alpha_i^* y_i K\left(x_i, x_j\right)+b^*\right). \tag{6}$$

The generator classification function is used to pre-classify the data in images training base, so as to judge the correlation between the training images and target images.

3 Face super-resolution reconstruction based on SVM-improved learning

Face super-resolution reconstruction means to estimate HR face by LR face, which is an application of imaging super-resolution technology in face area. As a kind of special image, due to the conspicuous structural features in face images, so the super-resolution algorithm adapt to common images can get a better effect in face reconstruction by combining these priori features. It is also widely applied in computer visual video surveillance, such as the field of video surveillance, usually the location of camera is quite far away from the face, so the captured face images are quite small. In order to better identify images, we first enlarge the face by super-resolution, then identify them, or doing the enlargement and identification at the same time.

Existing example-based learning face super-resolution reconstruction method uses the relation between the LR images and corresponding HR images in Markov network learning sample-base, then restoring the high-frequency details of input LR images through the relation we learned. This algorithm needs to build a huge face sample-base and do the traversal search in it. The HR sample can be the high-frequency details of the LR sample to restore the face. If and only if the searched face sample is similar to the input image sample and there is continuity in the content between corresponding HR

sample and other HR samples whose spatial position is contiguous, this HR sample can be the high-frequency details of the LR sample to restore the face. The searching process of the large-scale training sample base not only causes the time-consuming but also the mismatching of the search result will reduce the final quality.

According to the problems above, this paper proposes a face super-resolution algorithm based on SVM-improved learning. According to the PCA feature of human face, images are pre-classified by the algorithm. Before the matching search, SVM will pre-classify the sample base. So as to effectively extract and reconstruct the sub sample base, which has similar feature in target PCA, the algorithm establishes a SVM predictor for each class sample. By training samples, the algorithm trains the predictor and restores the prior knowledge in the form of predictiors' parameters. The experiment proves that it is an effective face super-resolution restoring method.

3.1 FACE FEATURE EXTRACTION

Face recognition technology has a wide application prospect in computer vision, guest identity authentication, multimedia data retrieval and etc.; face feature extraction is a necessary key step in process of face recognition. The face feature, which is related to application area, can be quickly and effectively extracted; becoming a key point whether realizes face automatic identification. The extraction process of human face features is a basis on a process that a transformation matrix maps human face image vector into feature vectors. During the mapping process, identification information is closely related with the application domain (such as different types of facial expression) can be extracted. And a large number of other irrelevant information (such as eyebrows shade, mouth size etc.) are discarded. In order to turn human face vector into human face feature vector with transformation matrix, it uses large quantities of training sample (known as the expression of face image type) to extract algorithm from human face feature. Then more training samples better the feature extraction.

PCA (Principal Component Analysis) is also called K-L transform (Karhunen-Loeve transformation), this method is to find a subset of main components which has the statistical distribution's data set at random, and corresponding base vectors satisfy the orthogonality [8]. The original data set is transformed into principal component space, which makes the cross-correlation of single data samples decrease to the lowest point. PCA is a classical method of feature extraction and data representation; it is widely applied in pattern recognition and computer vision, and becomes one of the most successful face recognition methods. Due to the dimension of face image sample is very high, if we directly process face images, the amount of calculation is large and the running time is long, so in recent years many face detection and face recognition algorithms use PCA method to reduce dimension first, then use other methods to process more.

A face image with $m \times n$ is rearranged as a column vector with $m * n$ dimension by PCA method, then all of the training images can get a group of column vectors after that change: $\{xi\}, x_i \in R^{m+n}, i = 1, 2, \ldots, N$, among that, N represented the number of the images in training sample set. Treat images as random column vectors, and training sample set is utilized to evaluate the average vector μ and covariance matrix S_T :

$$\mu = \frac{1}{N}\sum_{i=1}^{N} x_i \,, \tag{7}$$

$$S_T = \sum_{i=1}^{N} (x_i - \mu)(x_i - \mu)^T = XX^T, X = (x_1, x_2, \cdots, x_n) \,. \tag{8}$$

Choose the projection matrix A corresponding to the first k and biggest eigenvalues of S_T . Equation (9) is utilized to reduce the dimension of original images:

$$y = (X - \mu) A_K \,. \tag{9}$$

After the eigenvectors of S_T are restored as image matrix, which is the standardized face. The basic idea of PCA is that approximating each face by the linear superposition of standardized face. And let these linear coefficients as face features, these features are used to classify. The way to classify face with the use of PCA technology is called Eigenfaces method.

3.2 PRE-CLASSIFICAITON OF SVM

If there are K kinds of images in the images training database, mark as $T = \{P1, P2, P3 \ldots Pk\}$, and have k semantic classifiers $\{C1, C2, C3 \cdots Ck\}$. For each SVM classifier, its training set $T = \{(x_1, y_1), (x_2, y_2) \cdots (x_n, y_n)\}$, (x_1, y_1) is the labelled sample image which is given beforehand. $x_i \in R^2$ is the PCA feature of images; $y_i \in (-1, +1)$, $+1$ means images contain PCA semanteme, -1 means don't. Achieve images' semantic classifiers by using SVM to train these samples, and then these semantic classifiers are utilized to distinguish the left un-labeled images.

In this paper, using LibSVM 3.0 software package developed by Professor Zhiren Lin [9] of Taiwan University as SVM classify platform. LibSVM mainly includes *svmscale*, *svmtrain* and *svmpredict* three functions. Among that, *svmtrain* turn to train samples, according to input vectors and specified classification to generate suitable classifiers; when the way of classification is unknown, *svmpredict* is used to make input vectors map to the inner vector space of models based on specified classifiers, to find its classification principles; *Svmscale* is mainly for regularization of

numerical value, numerical value regularize input vectors to the boundary where LibSVM is fit for processing.

Due to the diversity of kernel function, one of the main points of designing SVM is that choose suited kernel function and corresponding parameters. According to the research by Vapnik and others, different kernel functions have little influence on the performance of SVM, but it is crucial for the performance of support vectors classifiers to choose penalty coefficient and corresponding paremeters of kernel function. In this paper, we use radial basis function, which is widely applied:

$$K(x, x_i) = \exp\left(-\gamma |x - x_i|^2\right). \quad (10)$$

Net check search is used to cross-validation C and γ. Try each basic couple (C, γ), and then choose the couple of parameters with the highest accuracy rate during the cross-validation. During the cross-validationn over and over again, determine two parameters, based on 1-a-1 multi-classification method to train image samples.

3.3 SVM PARAMETER OPTIMIZATION AND TESTING HR IMAGES GENERATION

In RBF-SVM, we need to determine two parameters which are planning factor C and Gaussian width σ. For C, if $C \to \infty$, means the rules of classification will meet all of constraint conditions, not only enhance training time and complexity of training, but also make classification have over-learning's situation, which reduce its generalization performance. So the data range of C should meet the situation of TAR and TRR, in order to keep the generalization performance of classifier, we need to take value as small as possible. For the Gaussian width σ, if without some ask for algorithm, we just set a group of probable values through the experience, and solving in turn under σ, then adjust according to the answer.

Do the SVM parameter optimization through net check search method. Net check search is reached through specially quantize and partly optimize method of exhaustion. In the method of net check search, firstly, confirm the data range of parameters, and then confirm the step of take value. Each parameters can start from the beginning of take value, take value to the end according to step, after enumerating all of parameter combination, then based on corresponding evaluation criterion to assess classification result, to find the optimum parameter.

When the classification is completed, the algorithm will establish groups of predictor corresponding with samples in each region, each category corresponding predictor to that class, i.e. if the samples divided into several K class, the groups of predictors in this region ought to contain the predictors of this K class. Multiclass predictor consists of a group of sub predictor; each sample of base classes corresponds to a linear sub predictor. A group of predictors operate the combined prediction to construct multiclass predictors. When predicting, firstly input data coding by the generator codebook in the process of sample classification, namely classification. Then according to the category, the system selects the corresponding sub predictors to predict. The training process of multiclass predictors is the process of training each single sub predictor. After the completion of training the predictors, the parameters will be stored for guiding the super-resolution restoration which inputting low resolution image. After the completion of training multiclass predictors, the system will use the multiclass predictors to reconstruct the HR face image. By using the bilinear interpolation to magnify HR face image size, the system inputs the LR face image, which is used as the estimation of initial image, for super-resolution restoration. When inputting low resolution block, according to the region which it belongs, the corresponding predictors operate high frequency prediction. The high frequency information blocks, which produced by those predictors, will be used to add up to the estimation of initial images in order to form the outcome of HR face image, namely the realization of face image super resolution restoration.

4 Simulation result and analysis

Text images come from a subset of international standard face image database, including 200 people's images from 7 angers and 1400 pictures in all, which includes location parameter of eyes, noses, mouths and etc. for each face image. Before the experiment, do the image intensity normalization and geometric normalization (80×80 pixels per image).

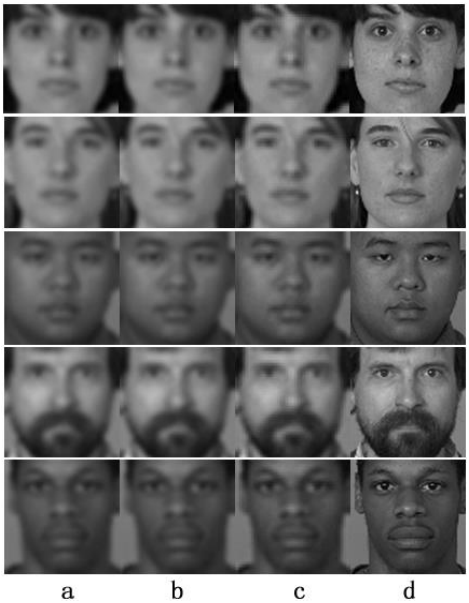

FIGURE 2 Reconstruction effects of three algorithms.
(**a** Freeman, **b** Reference [5], **c** Our method, **d** Original HD image)

Randomly choose 190 front view face images as training sample, PCA eigenvector is used as the input vector of support SVM, learning for the image categories,

pre-classify again based on output result. We choose the left 10 front face images in the database as text images, use a Gaussian blur template with the size 5×5 and variance $\sigma=0.85$ to degrade all HR images to the LR images with 40×40 pixels through Gaussian blur and down-sampling.

Do the contrast experiment apart with Freemam algorithm and document algorithm. We test the five face images' reconstructed effect (Figure 2).

As shown in these images, Freeman's algorithm [10] is the simplest, but the effect is poor. The algorithm of reference [5] is better in the central area of human face, but the other part especially the edge of face is fuzzy. Our approach is better than the first two algorithms in visual effect, but the edge of face and hair line still have some masks.

The value of PSNR is used to compare then text images' objective effect. Generally speaking, the higher value of PSNR is, the less distortion of image is. See Equation (11).

$$PSNR=10\times\lg\left[\frac{\left(2^n-1\right)^2}{MSE}\right]. \tag{11}$$

In Equation [11], *MSE* represents the error of mean square between original images and processing images. The result of quantizing PSNR is shown in Figure 3. We can reach the conclusion that the PSNR values in our approach basically higher than the other two algorithms. What's more, calculating apart the running time of image super-resolution reconstructed procedure on Freeman and our algorithm by *tic* and *toc* function in Matlab, the running speed of this paper enhanced obviously.

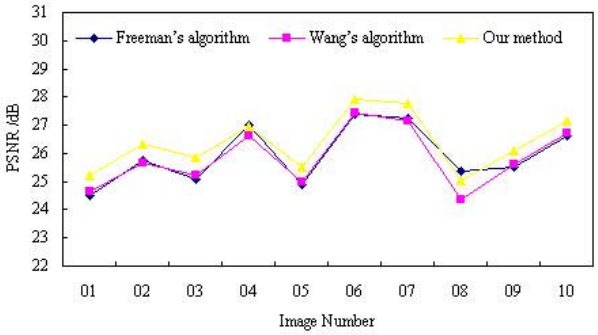

FIGURE 3 PSNR comparison of three algorithms

5 Conclusions

In this paper, SVM algorithm has been applied to example-based human face super-resolution reconstruction, which is a new attempt. SVM is used as the training classifier because its sample learning ability is very strong. We pre-search the sample database by defining PCA feature, find the sub-sample database whose feature is similar, then do the pixel-level exact matching search in the sub-sample set. The experiment shows that our approach can effectively reduce the mis-matching of image patches, save the running time and reach a higher quality in the reconstruction. In both subjective and objective way, restored image is better than the classical insert algorithm and the learning-based super-resolution method, and in the meantime the program running time is effectively improved.

Abstract

The master-slave bevel gear pair of some automobile rear axle is used to be as the research object, to obtain the image of the gear meshing contact region. Firstly, get the grey image of HSV space from RGB image to HSV space by the pre-processing algorithm; secondly, segment features of image accurately by the adaptive threshold segmentation algorithm; thirdly, fill the holes in the image of meshing region perfectly by proposed holes repair algorithm; fourthly, mark all connected domains of image with 4 -adjacent points domain labelling algorithm; finally, the Marking image area, width and the ratio of width and height features are selected to extract the image of the gear meshing region to obtain the geometry information of the gear meshing region. Research results show: contact centre E/L should be in 45% ~ 50%, and the length of the contact region B/L should be in 45% ~ 55%.

Keywords: HALCON, dry cutting gear, contact region, Image processing

1 Introduction

Dry machining is one of the development trends of metal cutting processing in the future. In recent years, especially the developed industrial country, gave great importance to the dry cutting. The quality of dry gear machining affected the performance of the gear transmission. To analysis the change of the meshing contact region before and after heat treatment, guarantee the system stability of the technological process for the dry cutting gear, the research group used Gleason Phoenix dry cutting machine to the master-slave bevel gear pair of some automobile rear axle, used as the study object.

The gear teeth surface contact region refers to the overlay of the contact lines on the gear meshing tooth's surface. The size, shape and position of the contact region not only reflect the manufacturing precision of a single gear, but also reflect the installation and transmission accuracy of the gear pair [3], which affect the bearing capacity, service life, quality and efficiency of transmission and noise etc. Therefore, scholars both at home and abroad, Litvin studied the dynamic performance of gear transmission for the teeth surface contact region [4], developed the theory of face gear transmission point contact. However, the reports are being rare by image processing technology, to analyse the size, shape and position of the tooth surface contact region.

In this paper, with HALCON image processing software, and through analysis the dry cutting gear meshing teeth surface image of the automobile rear axle, extract the grayscale image of HSV brightness space; use the adaptive threshold segmentation, holes filling algorithm and feature extraction algorithm to get the accurate geometry data of the gear meshing region; obtain the change of contact region before and after heat treatment; give the proportionality range of the required contact region for the final qualified products; and provide the basis of dry cutting gear manufacture.

2 Processing of the contact region image data for dry cutting gear before and after heat treatment

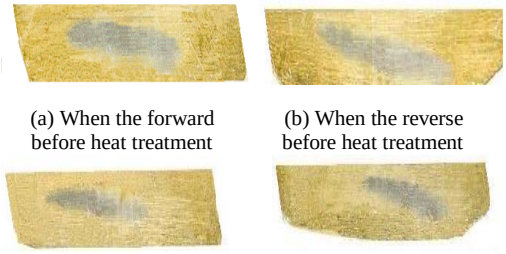
2.1 IMAGE ACQUISITION OF CONTACT REGION

During wet cutting manufacture, because the spiral angle change of big gear is smaller, change of the contact region in the tooth length direction is affected primarily by a small gear, namely, the forward surface turns towards the small end, and the reverse surface to the big end after heat treatment.

In order to get the meshing marks in the contact region of the master-slave bevel gear teeth surfaces, a thin layer of butter smears on the slave bevel gear tooth's surface, some resistance loads on the slave bevel gear to rotate the master gear in the positive and negative two directions, and then the imprinting is observed. Figure 2 shows the meshing contact surfaces image of the big gear tooth's surface before and after heat treatment twice, for the master-slave bevel gear pair of automobile rear axle. This system adopts high resolution digital camera (DH - HV1302UM) to collect images, produced by the Beijing DaHeng Company, a resolution of 1280 x 1024, and which is equipped with the image acquisition card, to

* ***Corresponding author*** e-mail: 394262133@qq.com

obtain images. The images of a tooth surface contact region for the gear are shown in figure 1.



(a) When the forward before heat treatment (b) When the reverse before heat treatment

(c) When the forward after heat treatment (d) When the reverse after heat treatment

FIGURE 1 The image of the teeth surface contact zone before and after heat treatment

Seen from Figure 1, there are the fixed contact regions on the tooth's surface for the different gear meshing. Through the information processing of those contact regions, the gear meshing situation can be obtained, thereby the gear machining and assembly process can be improved.

2.2 PROCESSING ALGORITHMS OF CONTACT REGION IMAGE

When measuring the gear contact region, based on the characteristics of the bevel gear meshing, some parameters are designed in this paper: L: the length of teeth, B: the length of contact region, E:, the distance from the centre of the contact region to the gear head, details is shown in figure 2.

FIGURE 2 The measured data of the contact region

2.2.1 Image transformation from RGB to HSV

Seen from the image of the gear meshing contact region, the boundary is fuzzy between the contact region and the contact region. It is difficult to identify the edge of the contact region accurately with the image segmentation algorithm. Even the owe or excessive segmentation problems may be lead [1]. The grey value of the contact region image and the background is close, when the colour image of the gear meshing contact region is transformed into the grey image. For this phenomenon, the grey value segmentation method is not good. According to the characteristics of the gear meshing contact region image, this article proposed algorithm based on HSV space V component to segment the gear meshing contact region image, and obtain the geometry information of the contact region.

The colour image segmentation algorithm based on HSV space in this paper, is aimed at the existing problem of RGB colour image segmentation, and combined with the three components in HSV colour space, which have nothing to do with the brightness. RGB colour space is converted to HSV space, there are:

$$\begin{cases} 0° & \max = \min \\ 60° \times \dfrac{g-b}{\max-\min} + 0° & \max = r, g \geq b \\ 60° \times \dfrac{g-b}{\max-\min} + 360° & \max = r, g < b \\ 60° \times \dfrac{b-r}{\max-\min} + 120° & \max = g \\ 60° \times \dfrac{r-g}{\max-\min} + 240° & \max = b \end{cases}, \quad (1)$$

$$s = \begin{cases} 0 & \max = 0 \\ \dfrac{\max-\min}{\max} & otherwise \end{cases}, \quad (2)$$

$$v = \max . \quad (3)$$

The following is the programs from RGB to HSV, the transformed images are shown in figure 3:

```
min = min(R,G,B)
max = max(R,G,B)
V = max
if (max == min)
S = 0
H = 0
else
S = (max - min) / max
if (R == max)
H = ((G - B) / (max - min)) * 60
elif (G == max)
H = (2 + (B - R) / (max - min)) * 60
elif (B == max)
H = (4 + (R - G) / (max - min)) * 60
fi
fi
```

Range of values: H = [0;2pi], S = [0;1], V = [0;1].

(c) When the forward after heat treatment (d) When the reverse after heat treatment

FIGURE 3 the bright image of HSV

2.2.2 The adaptive threshold segmentation

In figure 3, the bright image of the gear meshing contact region is obtained after transformation, which is already a

pair of grey image. To extract the information of the contact region, the binarization processing of the image should be done, which is the key is to choose a suitable threshold. Such as Otus, the image segmentation algorithm can be used to get the better threshold with the least squares principle value [2]. In figure 3, the boundary is not obvious between the contact region and the contact region. When the change of grey value is the smallest, the effects of image segmentation are not ideal. Its main reason is that every pixel point in the image segmentation process all adopted the same threshold. So this paper introduced the adaptive threshold segmentation algorithm, its basic idea is that the image are divided into several sub images; for the neighbourhood window which is determined by the centre of each pixel itself, the average value of all the pixels in the window is used as a threshold value [3]. If the pixel of this point is less than the threshold, then this point is set to 0, otherwise it is set to 255.So the threshold of the whole image is not fixed, but adaptive. In this way, the part is segmented completely. To get ideal segmentation results, the key is the select the smoothing filter size and threshold [4-6]. The results are shown in figure 4 (a) and figure 5.

2.2.3 Feature repairing: holes filling in a region

In region filling algorithm, in addition to the traditional scanning algorithm, Suzuki [7] proposed a method, which marks images and updates the array through the forward and backward scanning to decrease the scanning numbers of image greatly. Wu [8] during the linear scanning process, took into consideration the target pixel neighbourhood judging priority order, based on the different images which reduce the visits numbers neighbourhood and improve the scanning efficiency. He and others based on single linear sweep [9] and double linear sweep [10] of pixel neighbourhood characteristics, further development of this type of scan filling algorithm.

In region filling algorithm, in addition to the traditional scanning algorithm, Suzuki, [7] proposed a method, which marks images and updates the array through the forward and backward scan to decrease the scan numbers of the image greatly. Him and others, based on pixel neighbourhood features of single linear sweep [9] and double linear sweep [10], further developed the scanning filling algorithm.

In this paper, seen from the figure 4 (b), there region lots of holes and dispersed regions in the tooth's surface meshing region. These are adverse to extract the meshing region area information. So, firstly, holes need to be filled to maintain the integrity of the characters. The optimal neighbourhood region filling algorithm is adopted [11], and its calculation results are shown in figure 6 (a) and figure 7. Contrast the same region filling effect of figure 4 (b) and figure 6 (b), it can be seen that the algorithm not only ensure the accuracy of the gear meshing region edge image, but also fill holes in the meshing region image perfectly.

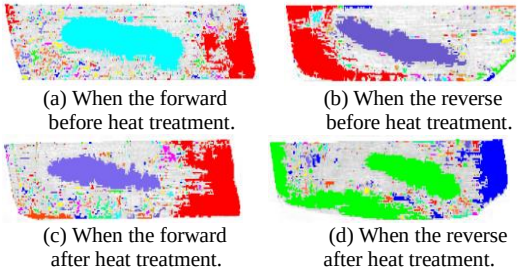
(c) When the forward after heat treatment. (d) When the reverse after heat treatment.
FIGURE 7 The gear meshing region edge image after fill holes

2.2.4 Mark connects demean each other

In figure 7, after filling holes, the contact un-contact regions (in the middle of the image) of the gear meshing are separated clearly, but there are many noise spot images at the un-contact region of the image, which are not benefit to extract image information of the contact area image. To distinguish the contact and un-contact region, so all connected domains are marked in the image with different colours, as shown in figure 8.



(a) When the forward before heat treatment. (b) When the reverse before heat treatment.
(c) When the forward after heat treatment. (d) When the reverse after heat treatment.
FIGURE 8 the gear meshing region image of mark connects domain

In this paper, 4-adjacent point region labelling algorithm is adopted, the steps are as follows:

1) Scanning image line by line, when the unmarked pixel point P is found, whose pixels value is 255, this point is set to a new ID.

2) Checking 4 -adjacent points of P, assign adjacent points to the same ID with P, whose pixels value is 255.

3) According to the step (2), check all adjacent points of marking pixels, and assign the same ID.

4) The repeating steps (3) do not be stop until all interconnection pixel points are marked.

5) Return to step (1), find untagged pixel points again, if found, then repeat the previous step (2) - (4), otherwise, the marking process is over.

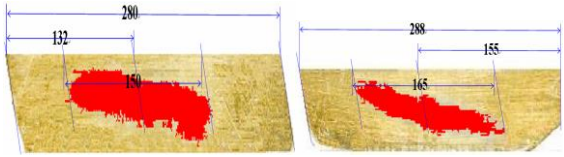
2.2.5 Feature selection and extraction

After the pixel connected domain, all obvious features (see figure 9) are connected into one region. Many connected regions are obtained. But only one is the desirable contact region image of the gear meshing. The image data of few larger regions in figure 9 and data analysis results are shown in table 1.

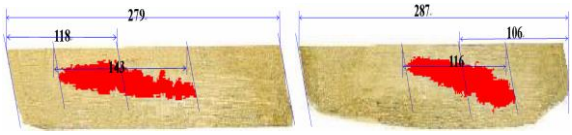
TABLE 1 Feature regional information and analysis

No.	Region	Width	Height	Width/ Height	Contact?
a	3046	150	41	3.7	Y
	1306	70	42	1.7	N
b	2376	165	36	4.6	Y
	2478	153	54	2.8	N
c	2060	143	27	5.3	Y
	2848	90	55	1.6	N
d	1837	116	36	3.2	Y
	2329	193	53	3.6	N

$$\begin{cases} 1500 < area < 3500 \\ 100 < width < 180 \\ 3.0 < \dfrac{width}{height} < 6 \end{cases} . \quad (4)$$



(a) When the forward before heat treatment. (b) When the reverse before heat treatment.



(c) When the forward after heat treatment. (d) When the reverse after heat treatment.

FIGURE 9 The final meshing region image and the analysis of Geometry data

3 The analysis and conclusions of experimental data

3.1 DATA ANALYSIS

Through the image processing of the gear tooth's surface before and after heat treatment, analysis results of geometry data information can be obtained and shown in table 2.

TABLE 2 Geometric data information analysis results of the gear meshing region image

	forward		reverse	
Design B/L	30%		30%	
	before the heat treatment	after the heat treatment	before the heat treatment	after the heat treatment
B/L	53.6%	51.3%	57.3%	40.4%
E/L	47.1%	42.3%	53.8%	36.9%

Data analysis shows:

1) The length of the actual contact region is longer than theoretical contact region;

2) After the heat treatment, the contact region is changed to the more narrow and shorter; as shown in figure 10, the forward surface is shorten about 3mm (7 pixels), and the reverse side is shorten the 20mm (47 pixels);

3) The forward and reverse surfaces are both moving towards the smaller end, where moving distance of the reverse surface is longer; as shown in figure 10, the forward surface is moving about 6mm (14 pixels), and the reverse side is moving the 21mm (49 pixels);

Through the above experiments, considering the change of the contact region in the meshing process, and the shape and position of the contact region of the final product, the general requirements of ensuring the contact region shall be as follows:

1) The forward surface: the contact region is above in the middle position of the tooth length and tooth root:

Contact centre E/L = 45% ~ 50%.

Length of contact region B/L is, generally in 45%~ 55%.

2) The reverse side: the contact region is slightly smaller than the end tip, and length slightly shorter:

Contact centre E/L = 40% ~ 45%.

Length of contact region B/L is about in 40%~ 45%.

3.2 CONCLUSIONS

In this paper, the meshing region image of the dry cutting gear for the automobile rear axle is studied by image processing technology. When the boundary is found to be the more vague between the tooth surface contact and un-contact regions, the preprocess algorithm is proposed to obtain the grey image in HSV space brightness; but the change of image grey difference is very small, the effect of the ordinary image segmentation is poor. In this paper, the adaptive threshold segmentation is used to segment features of the image; after image segmentation, there are lots of holes in the image, which are not benefit to extract

the area information of the meshing region. Holes must be filled. So the holes repairing algorithm are put forward to fill the holes in the meshing region image; all connected domains of image are marked with 4-adjacent points domain labelling algorithm; the marking image area, width and the ratio of width and height features are determined by the geometry information of every the connected domain; the final accurate image of the gear meshing region is obtained by three features.

According to the geometry data of the gear meshing region, the contact region change of dry cutting gear is obtained in the meshing process before and after heat treatment, and the required proportion range of the contact region shape and position is given to guarantee the qualified products, to provide the basis for dry cutting gear manufacture.

Abstract

An editing method of virtual human motion path based on movement cycle step-length is presented: it uses the Cardinal spline interpolation to extract the original path and equably sets the path editing control points; alters the positions of path editing control points to generate a new path and adjusts the position and orientation of the original motion sequence frame's root joint nodes on the new path; automatically judges any path curve segment that generates the problems of footstep disharmony after editing; for every incorrect curve segment, deletes the frames of general motion cycle step-length between the two path editing control points that contain incorrect curve segment based on the definition of motion cycle step-length and adjusts the spacing and moving direction of root nodes in every frame on the paths between the two control points; finally does constraint re-establish to all floor frames in the new path. The experimental results show that: the motion path editing method is simple and easy to operate. The generated virtual human motion is natural and smooth. It can effectively eliminate the footstep sliding phenomenon to improve the reusability of motion capture data.

Keywords: Motion path editing, Cardinal spline interpolation, Motion cycle step, Constraint reestablishment, Footskate cleanup

1 Introduction

Virtual human animation is to use a computer program or software to simulate the human motion. In the game and entertainment, simulation training and simulation tests based on virtual reality, such as virtual scene display, sophisticated skill training, virtual manufacturing and ergonomics analysis, it plays a more and more important role [1, 2, 3]. The motion capture technology means to use the data capture device to record some real human motion, and then map the recorded motion data to the virtual human in computer, to drive the virtual human moving [4, 5]. Because it has accurately recorded a wealth of detailed information and can efficiently draw realistic and delicate human motion, the technology has become the current study hotspot of virtual human animation. But it can only generate a particular human motion prior captured and the acquired data can only be applied in certain circumstances, which is not adaptable, of poor flexibility and with low reusability [1]. In the actual animation designs, human-body motion is rich and varied. If re-capturing the motions for every slightly differences of design actions, it will bring high costs. So, editing and addressing the existing captured motions to fit design requirement, to improve the reusability of captured data to reduce production costs is significant. The motion editing is an effective way of editing that changes other actions of virtual human as little as possible, and edits motion paths to fit animation design requirements of different trajectories under different situations.

But in the motion path editing process, it often generates the footstep slip phenomenon. Despite adopting many effective measures and methods, it is not well resolved. For example, Michael Gleicher had proposed a path transformation method. He used the arc length parameter to map the virtual human location to the new motion path. Then, he used the method of geometric constraints to define the double-foot position or relative position. But the resulted effect was not realistic [5]. In 2002, Michael Gleicher proposed a way to automatically recognize previous foot location constraints and manually edit and generate new foot position by users. This process did not introduce artifacts, but increased the labour input editors [6]. Noah Lock used an improved deformation technology approximating to rigid body to modify the motion paths, and time bending technology to allow users to concentrate on meaningful space path editing. Meanwhile, it automatically improved the motions, to regularly maintain a biomechanical relationship between the path shape and speed. But time bending technology has strict rules on speed, which makes its applicable scope limited [7].

Lu Xaojun used the joint interpolation method to generate each frame's joint parameter from the original captured data. It got the animations of different motion paths by interpolating values to the positions of motion locus of human body basis points. The process contained no foot position constraint and was prone to appear foot

[*] ***Corresponding author*** e-mail: wangwenju666@163.com

sliding phenomenon, making the generated animation on poor quality [8]. Liu Shuang proposed an improved motion path editing method: evaluating the foot position of original motion data for each frame to use as the initial constraints. Then, it automatically generated new constraint position of supporting point according to the motion direction changes. Following this, it would use the real-time inverse kinematics algorithm according to frame editing to solve constraint conditions [9]. In the motion path editing process, Luo Zhixiang established the appropriate objective function by defining a set of space-time constraint conditions and used inverse kinematic and numerical optimization method to solve the motion posture meeting the constraint conditions [10]. Chen Zhihua introduced the motion auto simplification technology into the conventional space-time optimization method and introduced the physical constraints into the conventional path transformation method, to guarantee the rapid convergence of the optimization process and the physical authenticity of the resulting motion [11]. However, in the above-described algorithm, it added the physical constraints containing velocity and acceleration. They were both non-linear functions. This would greatly increase the complexity of time-space optimization solution, and the overall solving speed is slower.

SAFONOV A [12] and some others put forward a search model based on the motion diagram that means to connect different motions by the way of diagram. Thus, it changes the motion path editing problem to the problem of finding optimal path according to the motion diagram. However, the effect of splicing and fusing the motion fragments is not satisfying and the mode needs to spend more time on fusing motions.

To solve these problems, here proposes a motion path editing method based on motion cycle step-length. It can effectively eliminate the footstep sliding phenomenon to improve the reusability of motion capture data.

The section 2 describes related work of the motion path editing algorithm; the section 3 describes some preliminaries as the theoretical basis of the algorithm; the section 4 gives a virtual human motion path editing algorithm based on motion cycle step-length; the section 5 is experimental results and analysis of our algorithm; the section 6 gives the conclusion.

2 Preliminary knowledge

2.1 FORMAT OF MOTION CAPTURE DATA

The file format of motion capture data mainly contains BVH, HTR, ASF / AMC. (In which, the BVH format developed by the Biovision is more common. This paper will take data on this file format as the input object of motion path editing.)

Analysing these human motion capture data, the content is mainly divided into two parts [13]: 1. data being used to describe the structure and the initial position of human skeleton; 2. recording a set of specific data for each frame including displacement of each root node in every frame under the global coordinate system and motion data information between adjacent joints as Euler angle and so on.

The hierarchical skeleton model is usually used to describe the human skeletal structure of the virtual human (as in Figure 1). The skeletal system is represented as a set of interdependent joint chains in the hierarchical skeleton model, and can be described as a tree structure (as in Figure 2). The root node of the tree is Root. Other nodes correspond to each joint of the human body model. The whole human motion can be seen as being composed by translation and rotation, that it is achieved by the translation of the root node and the rotation of the rest nodes relative to their parent nods on the tree. Wherein, the translation of the root node determines the motion trajectory of human, and the rotation determines the motion direction of human. Except the root node, the rotation of the rest nodes is done in the local coordinate systems which take their parent nodes as coordinate origin. So, in each frame of the motion sequence, the position of each joint node p_{n+1} in human model can be solved in the world coordinate system by the following formula:

$$p_{n+1}^{world} = \prod_{i=Root}^{p_n} T_i R_i p_{n+1}^{local} \tag{1}$$

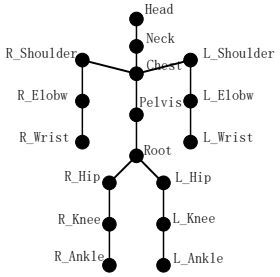

FIGURE 1 Structure diagram of human skeleton

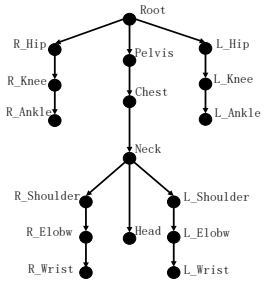

FIGURE 2 Hierarchical skeleton model of human

In the equation (1), p_{n+1}^{world} is the world coordinate of joint node p_{n+1}, p_{n+1}^{local} is the coordinate of joint node under the local coordinate system using p_{n+1} as origin and $T_i, R_i (i = Root, p_1, ...p_n)$ is the offset and rotation matrix of the child node relative to the parent node.

3 A motion path editing algorithm based on motion cycle step-length

In the motion path editing, it often appears a footstep slip phenomenon because of the original path changing. There are two main reasons for this phenomenon: 1. the location and motion direction of the virtual human are not timely adjusting. The total frame amount does not change, but the path length becoming relatively short after editing, that is, the relative distance between root nodes of motion sequence frames becoming smaller (what we called frame aggregation is too high). Their relative movement rate increases. But the step exercise frequency and step-length remain unchanged. These result the phenomenon of "out of step". 2. in the original motion sequence, a supporting point (i.e. a foot) is at the same position in space on two or more continuous moments. However, after motion path editing, the position of the supporting point has changed on the corresponding moments. If still using the original motion frame sequence to draw, it will produce footstep slip and appear motion disharmony.

To solve the footstep slip phenomenon, the new motion path editing method is proposed from these two areas. The algorithm steps are described as follows:

(1) Here takes global offset of each frame's root joint node in accordance with the Cardinal spline interpolation to extract the original motion paths and save, and calculates the slope of the spline interpolation curve of each frame's root node as a motion orientation.

(2) Evenly setting the path editing control points on the original motion path and taking two adjacent path editing control points as the starting terminal and ending terminal of a curve segment, by this it divides the original motion path curve into a number of curve segments. For each curve segment, along with the direction of human motion and with each path editing control point as starting point, it will find starting frames of each general motion cycle step-length in turn.

(3) It changes the location coordinates of the path editing control point, then rebuilds a new motion path by Cardinal interpolation, and adjusts the position and motion orientation of each frame on the new path.

(4) On the newborn motion path, here determines the curve segments with footstep disharmony phenomenon to construct the corresponding curve segment collection. If the curve segment collection is empty, namely no curve segment with footstep problem, then it directly turns to step (8).

(5) Here selects a curve segment with the phenomenon of footstep disharmony from curve segment collection. And it judges whether there is a general motion cycle step-length within the curve segment, if no, reading the next curve segment, Otherwise, starting to count the number of the to-be-deleted general motion cycle step-length on the curve segment. It assumes the curve segment on the original motion path which uses two adjacent control points as terminals AB, and the curve segment after path editing as AB'. The number of to-be-deleted general motion cycle step-length is calculated by equation (2), where λ is the general motion cycle step-length.

$$N' = \left\lceil \frac{\left| AB - AB' \right|}{\lambda} \right\rceil \tag{2}$$

(6) According to the number of to-be-deleted general motion cycle step-length in the curve segment, it will delete the frames of general motion cycle step-length between the frame sequences where the two control points are.

(7) It finds the nearest two editing path control points in the newborn path. The curve segment taking the two control points as terminals should contain the curve segment with the phenomenon of footstep disharmony. Between the two control points, it adjusts the frames that has deleted the general motion cycle step length. Checking if all the curve segments with the phenomenon of footstep disharmony have been treated in the curve segment collection, if still existing untreated curve segment, it turns to step (5), otherwise to step (8).

(8) It constrainedly reestablishes all the foot landing frames in the newborn path.

3.1 PATH EXTRACTION METHOD BASED ON CARDINAL SPLINE

To edit the motion path of virtual human, it has to extract its motion path from a section of known motion capture data. The new motion path extraction method based on Cardinal spline interpolation is as follows:

(1) On the equal time interval frame in the original motion sequence, it takes the global offset of root joint node as the position of Cardinal spline curve control point.

(2) For the translation trajectory of human root node, it carries out Cardinal spline interpolation to its horizontal axis component and longitudinal axis component (in the BVH files, because the world coordinate system is defined as the right-handed coordinate system and takes the positive direction of y axis direction as the positive direction of vertical axis, it takes the x axis component, z axis component as horizontal axis component, longitudinal axis component) conducting curve fitting to generate the original motion path.

In the process of extracting the original motion path, here selects the Cardinal spline interpolation because the slope of control points can be obtained from the coordinates of two adjacent control points and easy to implement. It assumes that $p(u)$ is the parameter cubic function between the two control points p_k and p_{k+1}. The four control points between p_{k-1} to p_{k+1} are used to

establish the boundary conditions of Cardinal spline segment [14], see equation (3):

$$\begin{aligned} p(0) &= p_k \\ p(1) &= p_{k+1} \\ p'(0) &= \frac{1}{2}(1-t)(p_{k+1} - p_{k-1}) \cdot \\ p'(1) &= \frac{1}{2}(1-t)(p_{k+2} - p_k) \end{aligned} \tag{3}$$

Then, the curve passing the two control points p_{k-1}, p_k can be noted as equation (4).

$$\begin{cases} p(u) = (-su^3 + 2su^2 - su)\,p_{k-1} + [(2-s)u^3 \\ \quad + (s-3)u^2 + 1]p_k + [(s-2)u^3 \\ \quad + (3-2s)u^2 + su)\,p_{k+1} + (su^3 - su^2)\,p_{k+2} \cdot \\ s = (1-t)/2 \end{cases} \tag{4}$$

According to equation (4), similarly the curve segment can be calculated passing p_k, p_{k+1} and the one passing p_{k+1}, p_{k+2} . Analysing this equation can get a certain interpolation curve of the curve segment that requires the coordinate values of four control points $p_{k-1}, p_k, p_{k+1}, p_{k+2}$ to obtain, so the original path is generated by combining groups of interpolation curves taking 4 control points as a unit, as in equation (4). In this formula, $u \in [0,1]$ and there is a variable t to control the tangent tensor of the being calculated spline, where t values zero.

3.2 SET OF PATH EDITING CONTROL POINT AND DEFINITION OF MOTION CYCLE STEPLENGTH

The step of evenly setting editing path control points on the original motion path is:

1. The number of user-defined path editing control points is N, $N \geq 4$, using the starting point and end point of the original motion path as the first and the last path editing control points, and it determines the time interval $\Delta t = frame\,time$ between frames of the original path (reading from BVH file) .

2. It calculates to determine the frame n_i where the i -th path editing control point located, in order to achieve an even set of the path editing control points. Wherein, $n_i = (i-1) \times \left\lfloor \frac{n}{N-1} \right\rfloor, i = 2 \cdots N-1$, n is the total frame number of the original motion sequence.

In the method above, it is about to remove part of the frames, to reduce the relative velocity between the root nodes of the frames. But if optionally removing a certain frame, it may cause incoherence of the motion action. We find that in most of the motion capture data there exists walking, running, small stride jumping and other actions. And actually, these actions are simple cyclical motion, such as walking that the action that left foot moves a step and then the right foot moves another step which can be regarded as a motion cycle. In order to keep the drawn motion action still smooth and continuous, after removing several sequence frames, we can take the motion cycle as a unit for deletion treatment to reduce the problem of motion actions excessively concentrating.

It defines the motion cycle step-length as follows: Any frame in which the left foot begins to lift is recognized as the beginning of a motion cycle. Through the left foot landing, and the right foot lifting and landing, the frame in which the right foot begins to land is defined as the final of the motion cycle. The spacing (in the plane of x, z) between the root nodes of the beginning frame and the final frame in the motion cycle is called the motion cycle step-length λ , as in Figure 3. Based on the definition of the cycle step-length we can also define the half-cycle step-length: Between the first frame any foot begins to lift and the first frame this foot lands and the other foot prepares to lift, the spacing (in the plane of x, z) between their root points is called the half-step-length of motion cycle, noted as $\lambda/2$.

Of course, it should be noticed that in a motion cycle step it may exist two cases as following. In Figure 3, if at the landing points p_{i1}, p_{i2} of the left and right foot, respectively comparing with the first frame the left or right foot lifting in the half-step-length containing these points, the human motion direction does not change to be a linear type or changes a small angle (≤ 60 degrees), it's called the general motion cycle step-length; If at the landing points p_{i1}, p_{i2} of the left and right foot, the human motion direction changes greatly(> 60 degrees), it's called special motion cycle step-length. To keep the important details of motion after editing, we will take the general motion cycle step-length as deletion objects.

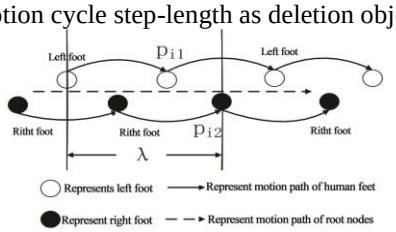

FIGURE 3 Motion cycle steplength

3.3 EDITING OF MOTION PATH AND FRAME ADJUSTMENT

In this paper, the path editing is realized by changing the position coordinates of the horizontal axis component and longitudinal axis component of path editing control points. In that, it does not change the vertical axis component to avoid artificially causing the phenomenon of feet suspending, feet into the ground and other issues. Therefore, it can only generate new motion path by carrying out Cardinal interpolation on the adjusted path

editing control point coordinates in the plane of horizontal axis and longitudinal axis.

It still needs to determine the position and motion orientation of each frame on the new path. The location treating process is as follow: the known number of original motion sequence frames is n, the number of path editing control points is N, and then it can calculate the incremental step length $step = (N-1)/n$ of u. Due to equation (4), in the curve segments $p_{k-1}p_k$, $p_k p_{k+1}$ and $p_{k+1}p_{k+2}$, every time u adding $step$ getting a point, separately calculating the horizontal axis and longitudinal axis coordinate components of the points, that is the location information of a certain frame root node in the new motion obtained by editing motion path.

About the adjustment of the human motion direction, it is known that in the motion path the motion direction of human at a certain moment is related to the slope of its position in the curve segment at that time. To this end, we will use the slope of each frame's root node position in the curve segment as the orientation of virtual human at this moment. So after editing the motion path, the position of the root node at time t also needs to be adjusted by changing of curve slope.

3.4 JUDGEMENT OF PATH CURVE SEGMENT ARISING FOOTSTEP DISHARMONY PHENOMENON

In the process of motion path editing, if the path change results in the moving velocity increasing of the root node (i.e. the curve segment length of the edited human motion path which passes the two control points is shorter than the length before editing) and the number of footsteps remains unchanged, it will cause footstep disharmony phenomenon, as in Figure 4. A, B are two adjacent edit path control points. L is the curve segment length of original motion path which passes these two points. L1 is the curve segment length of edited motion path which passes these two points. If $L_1 < L$, and because the number of frames between A, B is a fixed value, the moving velocity increasing of root node will surely cause the footstep disharmony phenomenon.

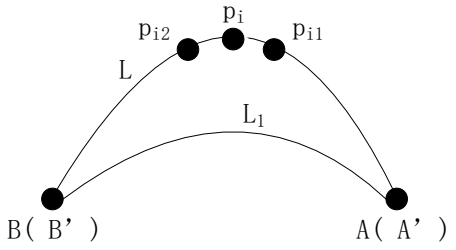

FIGURE 4 Variation diagrams of motion path before and after editing

Method of judging the specific curve segment arising footstep disharmony phenomenon in the motion path curve:

(1) It finds the root node collection $\{p_1, p_2, \cdots\cdots, p_n\}$ in the original path with the slope $k = 0$, and selects root node p_i from the collection in turn.

(2) It selects two frames which are $\pm m (5 \le m \le 10)$ frame away from the frame where p_i is. It calculates the slope k_{i1}, k_{i2} of root nodes p_{i1}, p_{i2} of these two frames in the original motion path curve and the slope k'_{i1}, k'_{i2} in the edited motion path curve. If one of k'_{i1}, k'_{i2} is positive and the other is negative and $k_{i1} \ne k'_{i1}, k_{i2} \ne k'_{i2}$, it executes (3), else it goes to (5).

(3) In the original path, that takes p_i as center to determine the two nearest control points A, B in the curve segment which passes the three points p_i, p_{i1}, p_{i2}.

(4) It calculates the curve segment lengths AB, AB' on the original and the edited path between the two control points A, B and the difference of the two lengths. If $AB - AB' > 0$, the curve segment in the edited path will arise footstep slip.

(5) Returning to (1), until finishing traversing the root node collection with the slope $k = 0$, the judging method ends.

3.5 ADJUSTMENT OF FRAMES AFTER REMOVING CYCLE STEPLENGTHS

In the newborn path, the specific method of adjusting two adjacent editing path control nodes after removing general cycle step-length can be illustrated by the following example. It assumes A, B are two adjacent editing path control points in the curve segment, which has been determined existing footstep slip phenomenon and noted as A', B' in the edited path. E, F is starting frame and ending frame of the N' to-be-deleted motion cycle step-lengths. $C(C'), D(D')$ are the editing path control points nearest to $A(A'), B(B')$, as in Figure 5.

(1) It separately calculates the number n_{EF} of to-be-deleted frames in curve segment EF. In the curve segment $C'E$ there contains $n_{C'E}$ frames. In the curve segment FD' there contains $n_{FD'}$ frames.

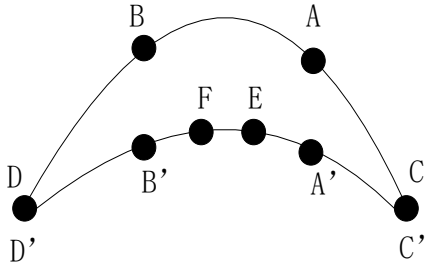

FIGURE 5 Removing Step-length

(2) It calculates the time T_{EF} that the frame sequence contained in curve segment EF spends for broadcasting, the time $T_{C'E}$ that the frame sequence contained in curve segment $C'E$ spends for broadcasting, and the time $T_{FD'}$ that the frame sequence contained in curve segment FD' spends for broadcasting.

(3) After removing the cycle step length in EF, it adjusts the interval length of the frames in $C'E$, FD' by equation (5) (6) to make it smooth and continuous.

$$j_i = \left\lfloor i \times \frac{T_{C'E} + 1/2\, T_{EF}}{n_{C'E} \times \Delta t} \right\rfloor \quad i = 1,2,3 \cdots\cdots n_{C'E}, \tag{5}$$

$$l_k = \left\lfloor (k+1) \times \frac{T_{FD'} + 1/2\, T_{EF}}{n_{FD'} \times \Delta t} \right\rfloor + j_{n_{C'E}} \quad . \tag{6}$$

$$k = 0,1,2,\cdots\cdots n_{FD'}$$

The equation (5) represents: after removing cycle step length, it determines the frame number j_i how far the to-be-adjusted frame, which is i-th frame apart from C' in the curve segment $C'E$, will be apart from C' in the newborn motion path after editing. The equation (6) represents: after removing cycle step-length, it determines the frame number j_i how far the to-be-adjusted frame, which is the k-th frame apart from F in the curve segment FD', will be apart from C' in the newborn motion path after editing.

(4) It takes the position information and motion direction information of the root node on frame j_i or l_k, to be the position information and motion direction information of the root node on the i-th or k-th frame after removing general cycle step-length, and takes equation (1) to calculate the position information of each joint node in the frame.

3.6 CONSTRAINT REESTABLISHMENT OF THE FLOOR FRAME

In the original motion sequence, the positions of the end effecters (feet) at two or more continuous moments are at the same landing position in space. However, after treated by path editing, it will make the human feet in different positions at these few moments appearing the footstep slip phenomenon. In order to ensure the quality of motion actions unchanged before and after motion path editing, in the newborn path that has deleted the cycle step-length, and it needs to constrainedly re-establish the foot landing frames (floor frame) inside the half-cycle step-length in the original path.

The judgment of human foot landing is distance, to check if the vertical distance between foot and ground is close to zero. The determining formula is equation (7).

$$\left|\vec{d} \cdot \vec{n}\right| \le H \ . \tag{7}$$

In equation (7), $\vec{d}$ represents distance vector from end effecter (foot) to the ground, $\vec{n}$ represents vertical unit vector and H represents the set threshold of landing detection. After landing detection, it will get the serial numbers of those frames at the foot landing moment. This allows the frame of the original motion sequence to classify, taking half-cycle step-length as unit to establish a collection S_L of frames of left foot landing moments and collection S_R of frames of right foot landing moments as landing constraint frames.

Setting the position of foot in the first landing constraint frame inside every motion half-cycle step-length on the new path as the position of foot in all the landing constraint frames inside this half-cycle step-length, it uses per-frame Inverse kinematics (inverse kinematics edited according to frame) [15] to calculate the rotation changes of other joints nodes to meet the position requirement.

4 Experimental results and analysis

In this paper, it verifies the proposed virtual human motion path editing method based on the motion cycle step-length by experiment. Experimental environment: Operating system: Microsoft Windows XP; CPU: IntelQuadQ9550 2.8GHz; Memory: 3GB; Program compiler environment: Microsoft Visual Studio 2008. The Human body motion capture data is collected by the OptiTrack whole body motion capture system with 12 cameras by the frame rate of 60 frames/Sec, and is stored by BVH file format.

In reality, the human motion is often complex but not single cycle motion as walking, running, etc.. To illustrate the generality and the effectiveness of the proposed method, we take a motion capture sequence (as in Figure 6) with 740 frames mixed with walking and jumping by the right leg for verification. In 1- 660 frames, it records the walking action starting with left foot, In 661-710 frames, it records the jumping action by the right leg, and in 711-740 frames, and it records the action of left foot walking a step after right foot landing. In this hybrid action sequence, walking is general cycle action.

During the process of building original motion path, the root nodes of each frame are as control points of Cardinal spline curve. For the motion capture data is the BVH file format, it does Cardinal spline interpolation to the positions of root nodes in the plane xoz to obtain the original motion path, indicated by the solid line in Figure 7. Before editing the path, it selects 4 control points to be path editing control points from the original motion path which is a Cardinal spline interpolation curve. According

to the setting method of path control point in this paper: two control points are the starting terminal C (root node position of frame 1) and ending terminal D (root node position, frame 740) of Cardinal spline interpolation curve, while the other two control points A, B are the root node positions of 247-th and 494-th frames. Now, it edits the path by changing the positions of path editing control points: in the x axial direction, the point C moves 35 units down, the point A moves 140 units down, and point B moves 100 units down; in the z axial direction, point C moves 5 units to the left. The new motion path curve is generated by carrying out Cardinal spline interpolation to these four control points, indicated by dotted line in Figure 7. As shown in Figure 7, the two motion path curves are smooth, and the transition between action sequences of right leg jumping and walking frames is natural, indicating the effectiveness of the Cardinal spline interpolation for virtual human motion editing path.

FIGURE 8 Frame sequence of footstep disharmony phenomenon

That is shown in Figure 8 is a motion frame sequence generated after editing the path. In which, it is found that there happens significant footstep disharmony phenomenon from the 375-th frame to the 450-th frame and human action is not natural and smooth. The reason is because after adjusting the editing path control points neither root nodes position or root nodes orientation of each frame are adjusted, and the shortening of curve length between the two points causes the frame aggregation to be too high. So, firstly, after adjusting the editing path control points, the root nodes position and orientation of each frame must be adjusted. Secondly, the problem of frame aggregation being too high should be solved by cutting the general motion cycle step-length. According to the judging method of path curves existing footstep disharmony phenomenon mentioned in section4.4, it can automatically determine the footstep disharmony phenomenon occurs in the curve segment with the path edit control points A, B as endpoints. It's determined by: the length of the curve segment with the endpoints A, B is 531cm, and after path editing its length is 510cm, the curve length becoming shorter; while the slope of the 280-th frame is 0, and the slopes of the 275-th frame and the 285-th frame which are 5 frames away from that point at its both sides are one positive and one negative. The 280-th frame is just in the curve segment with the two paths editing control points as starting and ending. This illustrates that the proposed method in this paper can achieve the automatic determination of path curve segment existing footstep disharmony phenomenon.

In the path curve segment AB, there exists general cycle step-length, and the starting frame and ending frame of

the first general cycle step-length are the 300-th frame and 360-th frame in which the root nodes identified by points E, F are. According to equation (2), it can get the difference between the lengths of the curve segment with the two path control points as terminals before and after the path editing. The ratio that the difference is divided by the general motion cycle step-length λ (here sets λ to be 100 cm, and it can be adjusted according to the different motion human subjects) is 0.21. So, it should delete a cycle step-length that is the motion frame between the two points E, F . Then, according to equation (5) and (6) to adjust the position and orientation of the frames between the curve segments EC, FD, the result is shown in Figure 9. It can be seen from this that although this method deletes the general motion cycle step-length, it does not affect the animation effects of right leg jumping, and this hybrid motion remains consistent and smooth.

In addition, in Figure 9, we find no footstep slip phenomenon occurs after path editing. This is because it uses the equation (7) to find each floor frame, and using inverse kinematics to constrainedly re-establish, to make the foot in the frames of these types at the status of landing before and after path editing.

Of course, the algorithm can also be applied to other virtual human motion path editing which contains cycle motion such as running, jumping, walking and other complex motion. It can effectively remove footstep slip phenomenon to obtain satisfying human motion animation effect.

5 Conclusion

To improve the reusability of motion capture data, here presents an editing method of motion path: the Cardinal spline interpolation is used to extract the original path and set the editing path control points; it alters the positions of path editing control points to generate a new path, and adjusts the original motion sequence frame on the new path; it aims at the human foot disharmony phenomenon caused by the shortening of the motion path curve segment after editing path, based on motion cycle step-length, proposing the way of deleting the frame of general motion cycle frames and adjusting the root nodes of every frame which contains that curve segment and between the two nearest editing path control points in the motion path to remove it; finally it does constraint reestablishment to all floor frames with cycle step-length, to reduce footstep slip phenomenon. The experiment results show that: the motion path editing method is simple, with less calculation, and easy to operate. The generated virtual human motion is natural and smooth. It can effectively eliminate the footstep sliding phenomenon.

However, this method does not consider that in the motion process, with the dramatic changes of path curvature, the centre of gravity of virtual human will be shifting to cause the human body tilt phenomenon; and also does not consider the dynamic approach of human motion path when it meets obstacles. These two areas are the place that in the future we should work hard in.

Early fault warning mechanism based-on association rules in server clusters management system

Yumei Ning*, Zhenguo Ding, Ping Zeng

School of computer science and technology, Xidian University, Xi'an 710071, Shaanxi, China

Received 1 June 2014, www.cmnt.lv

Abstract

With the rapid development of Internet and business internal information technology, the problem of server cluster fault early warning becomes important in server clusters management. To solve the problem, a server cluster fault early warning system (SCFEWS) based on event association rules is presented. This system is mainly based on the fault event association tree. First obtain event relationship and association rules. Construct early warning events associated tree with system logs and association rules, and store it in binary tree linked list. Then by using the warning event filtering algorithm, redundancy fault early warning events are filtered out and only source event for early-warning notification are kept. Experiment shows the proposed algorithm can effectively improve the accuracy of fault location for server clusters management.

Keywords: Server Cluster, Early Warning, Fault Association Tree, Warning Event Filtering Algorithm

1 Introduction

With the rapid development of Internet and business internal information technology, enterprise server clusters are gradually used to store a big data processing to meet growing business needs. The server clusters size and the number of servers upgrade and expand constantly with the development of enterprise business. But an increasing number of server components makes server clusters management difficulty and improves the probability of server clusters fault at the same time, which bring tremendous challenge to the entire server clusters manageability. So it has great significance to improve the cluster service availability about how to guarantee the stability of the server clusters system and how to find and promptly remove the hidden dangers in cluster system before fault occur.

Now various faults in server clusters are usually detected and located manually lacking server cluster fault warning management mechanism. So it is the priority problem monitoring real-time status for server cluster resources and giving corresponding warning to the administrator. With faults warning system, administrator can monitor server clusters comprehensively, detect server clusters anomalies timely, locate the fault timely and accurately, take action to avoid or reduce the risk and prepare for effective response [1]. Nowadays, although the major IT giants have their own server clusters management system, it does not open to all. And there is no universal solution for server cluster faults warning.

Early Warning Systems play a highly critical role in monitoring, prediction and reaction on upcoming disasters [2]. Early Warning Systems are found in many areas: natural catastrophic detection [3, 4] of tsunami, flood and earthquakes; detection of sudden and significant economic changes [5]; engineering and scientific area [1, 6], etc. In spite of variations between monitored domains, their main goal is similar: to reduce economic losses and mitigate the number of deaths from disasters by delivering information which allows people and organizations to prepare for emerging disasters [1]. So Early Warning Systems can also be used in server cluster management. Upcoming faults can be monitored and predicted by using Early Warning Systems.

This paper presents a server cluster management system based on the idea of Early Warning Systems. In a Server Clusters Fault Early Warning System (SCFEWS) put forwarded in this paper, fault warning module not only monitor real-time status for server cluster resources but also send early-warning information to the administrator before a fault occurs. It guarantees the reliable and stable running and the processing big data of the server clusters system.

In this paper, SCFEWS based on the warning event tree is used to filter out triggered fault early warning events and retain only source event for early warning notification. And the destination is avoiding the redundant warning events.

The remainder of this paper is organized as follows: Section 2 describes the formulation of the fault early-warning problem in server cluster system. Section 3 gives a precise problem statement and details our algorithm of the SCFEWS. Section 4 is the experimental evaluation in a few respects: its performance and the validity. And the Section 5 concludes the paper with a summary of our findings.

2 The proposed algorithm

This paper presents a server clusters fault early warning system in network resource management, which relies on client agents [7, 8] and provides early warnings against equipment failure such as CPU utilization, memory utilization, disk space, etc.

2.1 EARLY WARNING SYSTEM

The basic idea behind early warning [1] is that the earlier and more accurately we are able to predict potential risks, the more likely we will be able to manage and mitigate disasters.

An effective early warning system needs an effective communication system. Early warning communication systems are made of two main components:

(1) Communication infrastructure hardware that must be reliable and robust.

(2) Appropriate and effective interactions among the main actors of the early warning process.

Communication infrastructure for SCFEWS uses intelligent mechanisms [9] for communication and scatter of fault alerts through agents on which the server clusters can be remotely monitored and managed. SCFEWS use association rules tree for fault prediction. With them SCFEWS can better guarantee the server clusters running stable and reliable.

2.2 EXPERT SYSTEM

Expert system is intelligent computing Machine application system that has a lot of specialized knowledge and experience. Expert System contains the following modules [10].

(1) The knowledge base, where the knowledge of experts is represented using rules, frames, semantic networks, and first-order logic based methods, etc.

(2) The working memory module that stores the input data and the information generated by the processing of rules.

(3) The inference engine where the processing of the rules and the reasoning of the Expert system take place.

(4) The user interface module facilitates the interaction between the user and the Expert system.

(5) The knowledge acquisition facility provides the user with appropriate useful tools during knowledge acquisition procedures.

(6) The explanation module allows the Expert system to present its reasoning regarding its conclusions.

The main components involved in Expert system are the knowledge base and the domain expert.

2.3 EVENT CORRELATION

Event Correlation is an important fault localization strategy. The basic idea is to correlate multiple events to a single concept to filter out unnecessary events and unrelated events, reduce the amount of information presented to the network administrator, and increase the semantic content of the information represented by the association process.

2.4 ALGORITHM DESCRIPTION

The thought of the SCFEWS is showed below. Please see Figure 1. Initial stage, there is small amount of the managed server clusters monitored by management centre. With the expansion of the managed server cluster scale, the probability of server cluster faults is increasing accordingly. Therefore, corresponding early warning notification should be sending out before a fault occurs. It is important finding usable system early-warning information from all monitoring information. Thus, with the warning notification system administrator can take early preventive measures rather than remedial measures before a server fault occurs. And that is the processing of SCFEWS. Thus, the system robustness and the scalability to manage server cluster fault are improved.

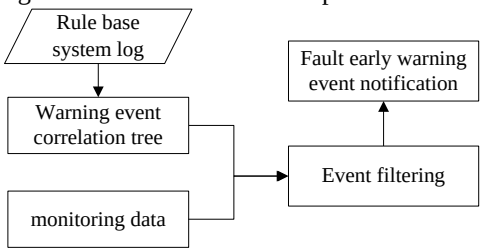

FIGURE 1 Structure chart of the SCFEWS

There are four mainly components in SCFEWS: the monitoring database, the warning event tree, event filtering module, and fault early-warning event notification module.

The monitoring data is comprised of server hardware such as temperature, fan, voltage, and power etc., system resources such as CPU utilization, memory utilization, disk space, and network speed etc., service resources such as processes, system services and application services etc. and network connectivity etc.

The warning event correlation tree is used to store the relationships between the various fault phenomena and is dynamically maintained for there is a certain correlation between various fault phenomena. The relationships data come mainly from the association rules for warning event and system logs.

Event filtering module: in server clusters, the generation of fault is often not a single fault phenomenon, but multiple fault phenomena occurring at the same time, that is to say cascading fault phenomenon caused by single fault. There is a certain correlation between fault phenomena, so event filtering module need to filter out triggered fault early-warning events and try to keep only source event for early-warning notification.

Fault early-warning event notification module sends the early-warning notification to system administrator for rapid positioning faults. And early preventive measures

are taken to prevent fault risk caused by server clusters before a server fault occurs.

3 Problem solution

The Server Clusters Fault Early Warning System (SCFEWS) aims to filter fault early-warning events according to generated warning event tree and try to keep only source of information for early-warning event for notification. The system consists of a server-side proxy equipment, communication modules and early warning systems management console.

The follow is the specific approach. Real-time monitoring various state of system equipment via proxy server clusters, storing all kinds of the collected information, judging its status data according to the threshold value. When monitoring event is judged to be early warning event, it will be encapsulated into object-oriented fault early warning event and delivered to early warning filtering module. Warning filtering module will filter out triggered fault early warning events according to generated warning event tree, and only retain source early warning event for notification of early warning event.

The emphasis of the SCFEWS is early warning filtering algorithm and the warning event tree with which early warning events is handled with.

3.1 ALGORITHM DESCRIPTION

Usually there are three main methods for early warning judging. They are threshold judging, Status Judgment and shazam judging. This paper uses threshold judging and shazam judging. Early warning judging [1] model is mainly responsible for processing the data obtained from the condition monitoring model. It judges the data according to the threshold value and quick change. When monitoring event is judged to be early warning event, the detailed event information will be encapsulated into fault event and delivered to memory fault events waiting for subsequent processing by early warning filtering module. Adopt object-oriented method [11] and construct quaternion form $E=(U,S,O,D,T)$ for storing early warning event-related information to descript the fault event in this paper. And symbol definition is as follows:

$U(U\text{ei})$: Identification of early warning events means such events is monitoring by the corresponding event listener for subsequent processing.

S=(Source) : Source of early warning events.

$O=(Object)$: Object of fault event. That is the fault device type.

$D=(D\text{escription})$: Fault description in detail, including fault identification, fault monitor and fault description, etc.

$T=(T\text{ime})$: Time for early warning events.

Early warning judging process is as follows:

(1) Get effectively monitor data from status monitoring model.

(2) Select the appropriate judging method based on monitoring data type.

(3) If the monitor data exceeds a threshold value or if it meets the fast changing limit, the monitor data is defined as early warning information and stored, else go to steps 1.

3.2 EARLY WARNING ASSOCIATION RULES TREE

When a fault event occurs in server clusters, it may cause other fault events closely related. There may be a relationship between them, such as time correlation, physical correlation [12], etc. Fault event sequence [13] is the combination of some fault events according to certain rules in a certain time interval.

Fault events associated tree is constructed based on the Fault event sequence in the rule base.

3.2.1 Get association rules

System administrators formulate relationship between warning events before server cluster fault early warning system is running, using algorithms inference log data and obtain relationship between warning events.

Association rules reveal the unknown dependencies between data items. According to the mining associated relationship, information from a data object can be used to infer the information about another data object [12, 13]. Describe as following.

Set $I=\{i_1,i_2,...,i_n\}$ is a project collection. X and Y represent item sets. X is the precursory item event and Y is the subsequent item event. Then Association rules is defined an implication relationship of the following forms: $X\rightarrow Y, where X\subset I, Y\subset I, and X\bigcap Y=\varnothing$.

3.2.2 Construct early warning events associated tree

Read the warning events association rules in rule base, according binary tree structure to construct and store the structure of early warning events associated tree. When management control starts, binary tree linked list is to be constructed and the warning events associated tree is to be generated according to the algorithm. Once relationship between early warning events in rule base change, the warning events associated tree need to be re-generated.

The node of early warning events is mainly composed of four components.

String *id* represents early warning event.

EventNode *child* represents the child node of early warning event.

EventNode *brother* represents the brother node of early warning event.

Variable *occur* represents whether the early warning event occurred. See Definition (1).

$$occur=\begin{Bmatrix}0,\text{event does not occur}\\1,\text{event occur}\end{Bmatrix}. \quad (1)$$

Binary Tree linked list for the early warning event is structured as follows in Figure 2.

```
public class WarningNode{
    String id;
    WarningNode child;
    WarningNode brother;
    int occur;
}
```

FIGURE 2 Warning node class

3.2.3 The algorithm of warning event correlation tree

Construct the algorithm of warning event correlation tree depending on the warning events association rules in rule base. Define *endFlag* to be the tag of scanning rule database. See Definition (2).

$$endflag=\begin{Bmatrix}0,\text{there exist unprocessed event}\\1,\text{scan end}\end{Bmatrix}. \quad (2)$$

The algorithm process is as follows:

(1) Generate Root node, set *endFlag* value to 1, and began to build children brothers linked list.

(2) Scan the rule base, add early warning event node whose precursor event is empty and subsequent events is not empty to the second layer of early warning events associated tree, and then set *occur* value to 1.

(3) Set *endFlag* value to 1, scan the rule base.

(4) If there is the early warning event node whose precursor event is not empty and *occur* value is 0, add the node to the sub-linked list of precursory early warning events node and set *occur* value to 1. If the node does not exist, the *endFlag* value will to be set 0 waiting for next scan processing.

(5) If *endFlag* value is 1, set all the warning events *occur* value to 0 within the linked list, scan end and the algorithm end. Go to steps (3) if *endFlag* value is 0.

3.3 EARLY WARNING EVENT FILTERING ALGORITHM

The early warning filtering algorithm need to depend on early warning association rules tree, and it mainly adopts the thoughts of expert systems. The aim of the algorithm is obtaining only source of information for early warning event for notification. Relying on early warning association rules tree, the algorithm filters all generated early warning events stored in filtering database, and eliminates redundant warning events.

The flow sheet for early warning filtering algorithm is shown in Figure 3.

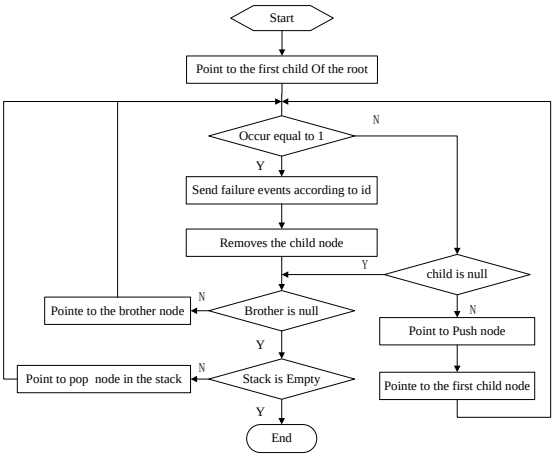

FIGURE 3 Flow sheet for filtering algorithm

The process of the early warning filtering algorithm description:

(1) Determine whether the event data in rule base changes.

(2) Call the early warning association rules tree algorithm and re-construct the warning event correlation tree, if the change exists. Call the warning event correlation tree constructed above, if the change does not exist.

(3) Traverse the warning event correlation tree, mark the warning event already stored in storage. Set variable *happen* value to 1.

(4) Traverse the warning event correlation tree using depth-first traverse principles. If there is a warning event whose precursor event does not occur or is empty, deliver it to early warning notification module. At the same time, if it has sub-event, remove all of its sub-events.

This paper uses a timer to trigger the early warning filtration module. The module will automatically carry out once filtering operation at regular intervals, and the administrator can set the interval. Finally the early warning event filtered will to be send to the warning notification module and there to be dispatched to administrator. Please see Figure 4.

```
LinkedList<WarnRule> events = new LinkedList<WarnRule>();
for(WarnNode w : events)
    markOccor(w);
Iterator<WarnEventRule> iterator = warnEventList.iterator();
filterEvent(iterator);
public void filterEvent(iterator<WarnRule> iterator){
    while(iterator.hasNext()){
        WarnRule occorRule=iterator.brother();
        if(occorRule.occor == true)){
            getWarnNodeSender().SendNode(changeWarnNode(occorRule));
            occorRule.child=null;
        }else  if(occorRule.child!=null){
            iterator=occorRule.child.iterator();
            filterEvent(iterator);
        }
    }
}
```

FIGURE 4 The early warning filtering algorithm

The early warning filtering algorithm can not only ensure the manageability of SCFEWS, but also ensure redundancy warning information not to be sent out.

4 Results

In order to verify the reliability of the Server Clusters Fault Early Warning System (SCFEWS), we programmed and simulated in the Network experimental Environment as shown in Figure 5. Management console was mainly consisted of management server and database server. Managed devices included five sets of managed servers, four managed PC and two mobile terminals. They were Lenovo IdeaCentre, AMOI N820 and IBM X5 respectively. The testing and analysis is only for server cluster fault warning system functional modules.

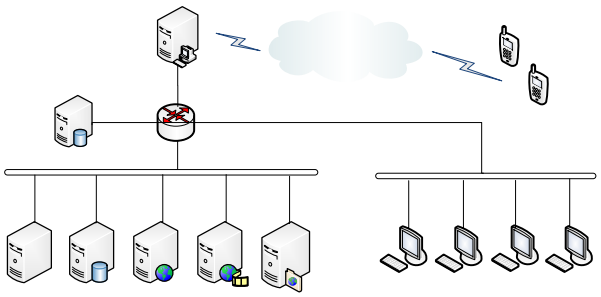

FIGURE 5 Network experimental Environment

For the convenience of testing the rationality and effectiveness of the model algorithm, the warning event correlation rules for the experimental system is part of preset in this paper as shown in Table 1. Program algorithm is omitted here.

The model algorithm is analysed from the performance, the warning filtration effect and the network utilization in the network experimental environment above.

TABLE 1 Correlation rules definition

No	Early warning UEI	Early warning description	precursory early warning	precursory early warning description
1	AgentDown	Client Agent shut down	DeviceDown	Server shut down
2	GetDataFail	Fault to getting data	AgentDown	Client Agent shut down
3	ServiceClosed	Host server is shut down	DeviceDown	Server shut down
4	DeviceUnreachable	Host network is unreachable	DeviceDown	Server shut down
5	ApacheDown	Apache Application stops	DeviceDown	Server shut down

Process is as follows: After the Device Agent of Managed device is launched, its various types of information is collected and incorporated into the monitoring database. If the monitoring data exceeds the defined threshold, then the event data is encapsulated into early warning and early warning is transmitted to the early warning filter module for pre-process based on the warning event correlation rules. And the early warning notifications being filtered are sent to the management client.

Experimental results show that the system is running continuously seven days in monitoring, during which the system produced a total of 44 early warning events. There are only 25 early warning events being warning information after filtering module filters the 44 early warning events, which is basically close to the original number of early warning events. Thus early warning filtration achieves a desired effect and the effectiveness of the warning filtering algorithm is proved in this paper. Please see Figure 6.

The following is the SCFEWS performance experimental.

Server is usually used to provide services. Because the proxy client software runs on the server equipment, and communicates with the management console, there must be low resource occupancy not to impact on performance of the server. So the CPU usage of proxy client and procedures network occupancy rate is experimented.

Server device can obtain CPU usage via top and other procedures when the proxy client software is installed on the managed device and turned on in the daemon. By setting the management console monitor polling cycle and sampling the CPU utilization, the CPU utilization of proxy client server is measured. Please see Figure 7.

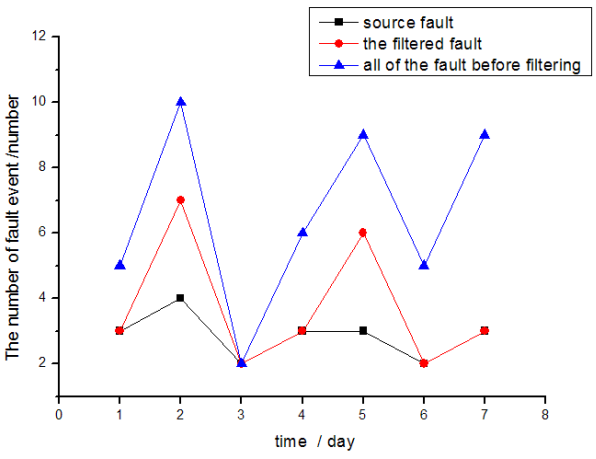

FIGURE 6 Comparison of early warning event

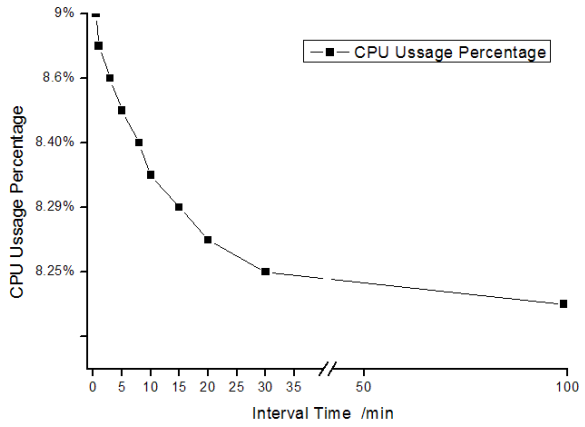

FIGURE 7 CPU utilization of server proxy client

It can be seen from the above figure that the monitoring polling cycle time is inversely proportional to the CPU utilization. Once polling cycle time shortens, CPU occupancy rate goes up. When proxy software is not running, CPU occupancy rate maintains at about 8.3%. When the proxy software is opened and the polling cycle is set to be thirty minutes, at this time, although management client does not send the command, the CPU utilization increases slightly for activity agent software monitoring ports and the activity agent process taking some of the resources. Along with shortened polling cycle, proxy software is more and more frequent to get early warning surveillance system data, so the value is also gradually increasing in CPU utilization. When polling cycle is set to half a minute, the CPU utilization maintains at about 9.0%. Thus the agent software on server equipment occupies very little CPU resources, and it will not have big impact on the server computing performance.

Server device can obtain the network rate via iftop and other procedures when the proxy client software is installed on the server device and turned on in the daemon.

Sampling the network speed during the agent software opening and the management end different monitoring polling cycle stetted, server agent can be analysed terminal network rate which is showed in Figure 8.

It can be seen from the above figure that the monitoring polling cycle time is inversely proportional to the network traffic. Once polling cycle time shortens, CPU occupancy rate goes up gradually. When proxy software is not running, network traffic maintains at about 0.28KB/S. When the proxy software is opened and the polling cycle is set to be thirty minutes, the network traffic decreases slightly around 0.31KB/S. Along with shortened polling cycle, network traffic is also gradually increasing. When polling cycle is set to half a minute, the network traffic maintains at about 0.8KB/S. Thus, the software routine has slight impact on the server computing performance when interval time is set a certain value.

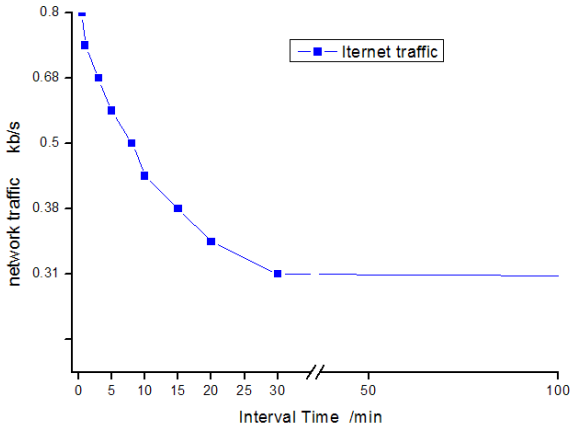

FIGURE 8 The network traffic of server proxy client

5 Conclusion

It can be seen from the above experimental data that the warning model algorithm presented in this paper has certain advantages in fault advance warning. The Server Clusters Fault Early Warning System (SCFEWS) designed in this paper integrating hardware status monitoring, system resource monitoring, early warning service monitoring, device control and device resource management has achieved the early warning and management of server clusters, also has not a major impact on the server computing performance. It greatly facilitates the operation and maintenance of the server clusters management. The algorithm has high value for reference to large-scale server clusters management.

The SCFEWS designed in this paper need to deal with system fault human involvement after the early warning events occur. Failover automatically and automatic downgrade functionality will to be introduced into early warning in the next research, trying early warning automated processing and restore.

A new dynamic regulation UIPO model of groundwater based on cloud computing and hydroinformatics

Wensheng Wang*, Huifeng Xue, Feng Zhang

School of automation, Northwestern Polytechnical University, Xi'an 710072, China

Received 3 March 2014, www.cmnt.lv

Abstract

In order to solve the problem of excessive mining of the coal resources in Yulin mine area caused enormous damage to groundwater and in turn threatening the regional sustainable development, proposed a new dynamic regulation UIPO model of groundwater, which combined hydroinformatics, cloud computing and multi-source data fusion algorithm, and the mine hydrogeological spatial database, the visualization of 3D geological model and groundwater dynamic evolution model are created. Simulation results show that the UIPO complete with these models and with groundwater - ecological environment - economy system model all connected data analysis for decision support system and with complete hydrogeological and spatial process method by means of big data, can simulate the temporal and spatial variations of groundwater resources, forecast future impact on Yulin mine area groundwater for sake of large-scale exploitation.

Keywords: hydroinformatics, cloud computing, groundwater, dynamic regulation, big data

1 Introduction

It is a very complex system engineering to dynamic regulation of groundwater resources [1], and integrated studies it involving cross between different disciplines. To effectively achieve the dynamic regulation of groundwater resources must first create the refinement of the dynamic control model. After 20 years in Yulin in the mining of groundwater resources monitoring period, the accumulated number of dollars in TB groundwater data assets and still maintain a geometric growth. These data include mining high-resolution remote sensing, InSAR, sensors and other monitoring underground mining "monitoring wells" information and "cadastral" information, including a diverse [2], heterogeneous, multi-scale spatial information. Faced with such a large scale, diversity and rapid proliferation of "big data", the model has not been available for large data deduction, making a simple mechanism based on the traditional assumption of certainty or aquatic ecosystem dynamics model approach has been limited.

So how to improve the "big data" management and service levels, to achieve its "crossover reuse" and "holographic visible" will be an important issue to realize mining groundwater resources dynamically regulated faces. Pressing need to design an application for large data natural sciences, social sciences and engineering disciplines fusion of dynamic regulation of cross-model integrated studies methods, to be able to effectively analyse "all data" relationship between groundwater mining "big data" and the ecological environment and socio-economic systems, so that show great value in use, can simulate mining temporal and spatial variation of groundwater resources, projections of future large-scale mining impact on groundwater, forming a technical methods and theoretical system and coupled ecological, socio-economic, groundwater "big data" decision support system dynamic regulation of groundwater resources.

This paper proposed and studied by means of information theory and method of water including cloud computing, networking, and big data analysis and other next-generation IT and the combination of three-dimensional GIS to solve the dynamic regulation of groundwater mining elm God unified model construction problems. Hydroinformatics methods have become a new trend in groundwater monitoring and numerical simulation of the ecological environment development. Foreign researchers have tried in the waters of rivers, groundwater, rainwater, water dynamics, water ecological environment to calculate [3], groundwater flow numerical simulation [4] variation of water environment [5], etc. into water information science, exploration of cross discipline between information technologies combined with the common water science. Now that the hydroinformatics is related to hydrological data management, analysis, water resources protection, investigation and assessment of water resources, it is very effective in hydrological models [6]. So, this article intends to use the hydroinformatics multidisciplinary and comprehensive features to create a dynamic regulatory model for groundwater resources in water-based informatics, combined with groundwater dynamics theory, create the basic framework for the evolution model of groundwater resources under conditions of coal mining activities associated with water cycle changes in the region, and then put forward have the versatility and

***Corresponding author** e-mail: wwsh2007@163.com

systematic UIPO (Unified-Input-Process-Output) conceptual model, it is a further foundation for the other models.

2 UIPO regulatory model based on hydroinformatics

This paper first carried on the dynamic monitoring method thorough analysis on groundwater hydrology spatial data, then the systematic research on the UIPO model, UIPO model framework, as shown in Figure 1, finally proposes the effective implementation method and experimental verification. The UIPO model mainly includes:

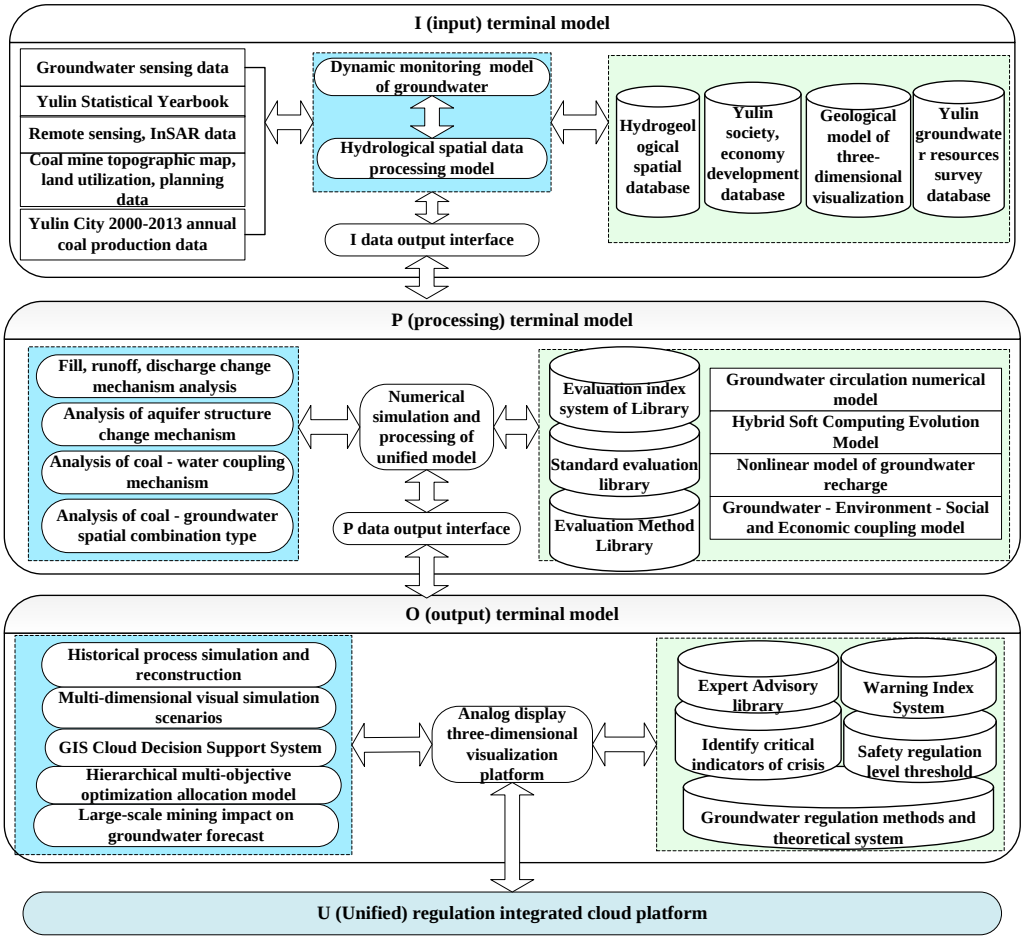

FIGURE 1 IPO model framework

2.1 CREATING OF A THREE-DIMENSIONAL GEOLOGICAL MODEL AND VISUALIZATION OF LARGE DATA PROCESSING HYDROLOGICAL MODEL SPACE

Effective realization of groundwater resources of refinement dynamic control problem was to obtain a large number of dynamic control data, In this paper, using of remote sensing, networking and a series of probing, testing techniques, to obtain the area aquifer hydrogeological parameters, create hydrogeological spatial database mining and visualization geological model, Build dynamic monitoring of groundwater resources and groundwater hydrology model space large data processing model, formation of I terminal model in UIPO. The main contents include:

1) The hydrological spatial data semantic modelling. Due to the diversity and heterogeneity of hydrological data sources a large space, research-based ontology semantic technology hydrological data for unified expression of a large space, to achieve an integrated processing, service publishing and storage technology for hydrologic data provide a large space data representation model.

2) Multi-source remote sensing data fusion model. Using of Yulin City TM images and MODIS images and Yulin 20 years of mining groundwater resources monitoring data and field data, based on pluralistic, multi-temporal, multi-scale, multi-source remote sensing image mining integration of heterogeneous data processing and evaluation techniques, The two information extraction and mining groundwater monitoring wells measured data from remote sensing

image analysis, generate the groundwater of multi-source remote sensing data fusion and monitoring model.

3) Dynamic monitoring model of groundwater. Groundwater resources in network research on perception, model structure, deployment framework, in order to realize the dynamic monitoring of groundwater resources, access to the aquifer hydrogeological parameter data fusion method, establishment of monitoring data based on D-S evidence theory.

4) A large space hydrological data processing methods. In order to meet the long-term dynamic monitoring of groundwater resources in the mining area, a hybrid cloud method of dynamic organization of information and structured, semi-structured and unstructured data storage model, Using NoSQL, MapReduce and machine learning techniques, structure support large data processing centre hydrological spatial data infrastructure, be able to multi-source, heterogeneous, lots of space for large hydrological data for dynamic organizations, the establishment of hydrogeological spatial database mining and visualization of geological models.

2.2 CREATING OF GROUNDWATER RESOURCES UNDER COAL MINING CONDITIONS ASSOCIATED WITH THE MINE WATER CYCLE CHANGES IN A DYNAMIC EVOLUTION MODEL

According to the key scientific problems of groundwater resource dynamic evolution system of mine hydrogeological characteristics, groundwater recharge, runoff and discharge characteristic, construct the index system, evaluation criteria and evaluation methods of evaluation, the formation of P terminal model in UIPO. The main research contents include:

1) Analysis of groundwater hydrodynamic field characteristics and evolutionary process. Using of historical data, related data model and I model output terminals nearly 20 years Yushen mining groundwater "recharge, runoff, discharge," the temporal variation, revealing the dynamic evolution of groundwater recharge. Dividing seams - a combination of the type of ground space, study the impact of coal mining impermeable layer stability, building evaluation index system, evaluation criteria and evaluation methods.

2) High Performance hybrid soft computing model. Study on groundwater dynamic process "recharge, runoff and discharge" model of temporal and spatial variation characteristics and mechanism, Create mining groundwater circulation numerical model and the dynamic evolution of high-performance mixed soft computing model to simulate groundwater mining cycle.

3) Groundwater recharges nonlinear model. Study on mining area containing variation of aquifer structure, groundwater recharge revealed qualitative and quantitative variation characteristics and formation evolution mechanism and time and space, a nonlinear model for mining area groundwater recharge aquifer structure change.

2.3 BUILD DYNAMIC CONTROL MODEL OF GROUNDWATER RESOURCES

Through the study of groundwater regulation methods and theoretical system, to build a unified regulation of groundwater comprehensive integration platform, achieve reasonable regulation of groundwater resources and the purpose of sustainable development and utilization. To form of O terminal model in the UIPO and U (Unified) control platform. The main research contents include:

1) Building of underground water resources regulation platform. Using of multi-disciplinary, multi-technology comprehensive integration and big data, cloud computing and other next-generation IT to create a "dynamic regulation of groundwater mining Yulin comprehensive integration cloud platform" (hereinafter referred to as U-control platform), realization of dynamic monitoring of groundwater and unified regulation. To create a unified mine three-dimensional groundwater flow model and mining groundwater flow - land subsidence coupling model on platform U-control, revealing the intrinsic link groundwater resources and water level changes between coal mining and land subsidence mechanism.

2) Groundwater regulation methods and theories. Based on the U control platform, using the P model output and the evaluation index system, evaluation criteria and evaluation method, constructs the groundwater of mining area ecological environment and social economy system is a complex coupling model of water resource optimal allocation model of multi-objective hierarchical; using GIS cloud data integration, statistical, spatial analysis, systems evaluation mining groundwater resources based on created three-dimensional visualization of the geological model and hydrological space large data processing model, building analysis based on all the data big data associated decision support systems. Affected by coal mining on water resources evaluation system, revealing the impact of coal mining on water resources and characteristics of the way to establish an expert advisory library. Based on the results of a variety of typical coal mining geological conditions were analysed to establish critical identity crisis groundwater mining index system, early warning indicators and safety regulation of groundwater level threshold.

3 Groundwater regulation of cloud computing architecture platform

In this paper, using of cloud computing solutions to build a data centre, including the design of a public and private cloud hybrid cloud groundwater cloud computing platform, as shown in Figure 2, Corresponding groundwater cloud storage can be divided into the

corresponding public cloud storage and private cloud storage. Public cloud built on the Internet, and to learn building a private cloud within the Intranet, both through a bridge (Bridge) before they can communicate with each other, the daily works of the two are physically isolated.

3.1 PRIVATE CLOUD PLATFORM OF GROUNDWATER REGULATION

Private cloud combines the realization of cloud computing technology and methods to focus on building the Intranet; you can realize the integration and sharing of groundwater data. With the inner scale geographic, geologic map superposition, fusion, and further can be related to the ongoing construction of potentiality assessment of mineral resources, reserves by using survey data integration and sharing.

Groundwater regulation of private cloud within the LAN using server clusters, storage devices, networking equipment and other infrastructure, Using virtualization software background memory, memory, CPU division, loading a different operating system [7], in which the deployment of geological database, application server software platform. But we can also use an application-level virtualization technology, virtual application table level, so that users can seem like using a local machine using a remote operating system, applications, and so on. Groundwater regulation database is a large logical database, is more centralized, distributed database cluster, while the actual database stored in the background groundwater regulation of cloud storage, the formation of Earth Science Data Centre Data Warehouse based on groundwater regulation. Groundwater regulation database data centre computing centres through groundwater regulation of WebServices provide all kinds of groundwater regulation outward data services supported by the SOA Manager GIS server as a spatial data services and computing services, and constitutes a cluster of servers. Because Web Services returned to the user is the result of converting it later, it effectively hides the pluralistic, heterogeneous raw data, to the integration and sharing purposes.

3.2 PUBLIC CLOUD PLATFORMS OF GROUNDWATER REGULATION

Groundwater regulating public cloud is constructed in Internet, will be able to open basic geographic, geologic map publishing network support for SOA GIS server, released to the public resource called API. Groundwater can be achieved in the regulation of public cloud services and the Azure service resources, shared resources (such as Google, ESRI spatial services, etc.) Internet converge on the interaction of groundwater can provide cloud computing services in the public Internet, and background data services, computing services, etc. can be flexibly increased or decreased according to demand, but can also be integrated with other systems.

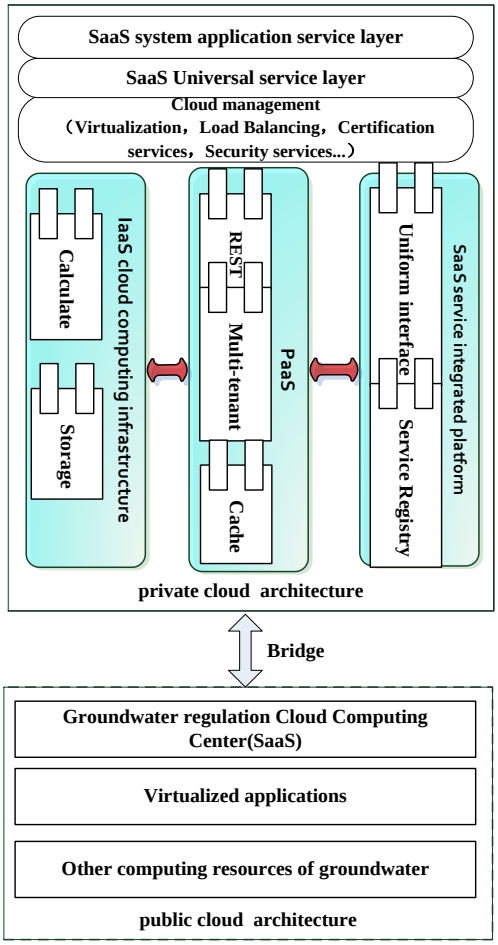

FIGURE 2 Load balancing test result

3.3 DESIGN AND IMPLEMENTATION OF VIRTUALIZED APPLICATIONS

In order for the existing hardware, software resources (genuine software can effectively solve the problem) were fully utilized, rational allocation of resources with virtualization technology, cloud computing applications using international recognized VMWare, Citrix, IBM and other virtualization products, building groundwater regulation of software and hardware resources virtualized application platform. Set one server into multiple virtual servers, we can also create a number on a single server or desktop level to achieve application-level virtualization application examples (the operating system can be Windows, Linux, Unix and other operating systems), managed by the virtual instance is ready to create a new instance of on-demand, upon request, and may also install supporting software. To meet people while online application, each person using different virtual instance, users can experience the benefits of virtualization vital brought. In a Windows operating system desktop virtual application instance, we can run ArcGIS, Oracle, Office and other software applications, and even the development of application software; Installing ArcGIS Server, Java EE applications on Linux and other

operating systems. An example in ArcMap version management software in virtualized applications, install all virtual instances share a license manager [9], log a user license is available subtrahend one, until exhausted. Data and applications can be separated or stored centrally. Backup mechanism virtual instance is optional, virtual instance can be unified updates and upgrades, updates and upgrades can also be customized, but all users do not need, all done on the server side, the user can at any location simply by browsing connected to the server can be achieved as local as processing data. Multiple servers reasonable allocation of hardware resources, which will be a server as a central node server virtualization, virtualization management platform to establish, manage multiple situated LAN, WAN physical servers or virtual servers [8]; We can use virtual machines, virtual desktops run in two modes. Virtual machine model is not installed on the client virtual machine, but according to the user's application, automatically creates a virtual machine installed on the server according to various software applications, databases, software development and other virtual machine template for applicants and assign the appropriate hardware resources (disk space, memory, network card, bandwidth, etc.).

3.4 DESIGN AND IMPLEMENTATION OF GROUNDWATER REGULATION OF BIG DATA CLOUD STORAGE PLATFORM

Use of Yulin City TB level storage device (the future will use PB grade, EB level or ZB level) to build groundwater regulation cloud storage, and expandable distributed storage nodes as the provinces. Using IBM, HP and other multiple servers form data storage pool, cloud storage device is a large physical storage device through optical fibre connection; Data storage uses zoning, fast file method, data access optimization in the interview. Taking into account the future internal and external services also needs to be divided into public storage cloud storage cloud, private storage cloud. Which is the corresponding public storage cloud computing external public cloud services, public cloud analysis, and private cloud computing is on a private cloud inside the private network, private cloud analysis. The groundwater regulation of big data cloud storage platform is as shown in Figure 3.

Data stored in the data warehouse using the form geosciences organizations, and is divided into content database, file databases, relational databases and object types, geological maps, gravity data, geochemical data, isotope geology of the work, geological work arrangements, as preserve the original format mining belt, administrative divisions and other data in a file database, so easy future use. These data systems data checking, cleaning, conversion, and unified loaded into Oracle spatial database, spatial data using the Oracle Spatial option to achieve. Fast indexing by using spatial index, and the objects in the database are saved in different tables paces, and a table space unified stored in the cloud storage device. Data storage uses parallel file system (Parallel File System) or concurrent file system, distributed file system, data management is the table. A key feature relative to the general system is the stand-alone file can store the same block of a file stored in the group of nodes, while allowing access to a number of computing nodes concurrently, without confusion and error, each node can use the own local file system, the establishment of efficient synchronization between each other and co-processing capabilities.

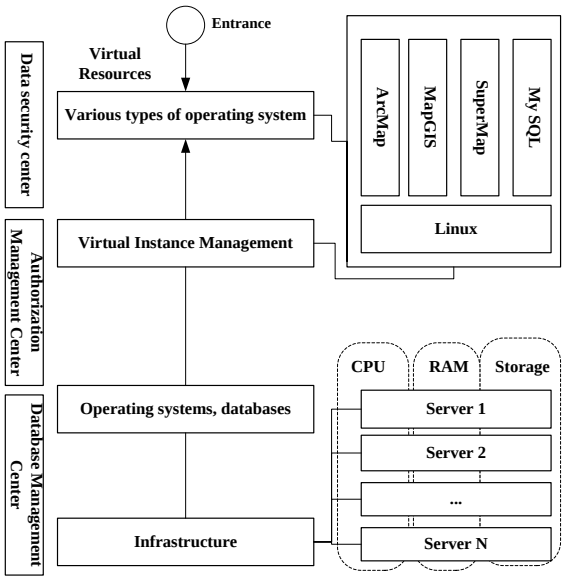

FIGURE 3 Groundwater regulation of big data cloud storage platform

3.5 MULTI-SOURCE DATA FUSION ALGORITHM FOR GROUNDWATER REGULATION BASED ON KALMAN FILTER

Mining groundwater regulation data involves the mineral resource potential assessment, field verification of mining rights, the extent of the work of geological data, geological work deploy data, geological maps and other data, the data is produced in different periods, data formats, and so have different spatial reference, the need for its data conversion, normalization processing operations. The original data on groundwater regulation database to keep a unified cloud storage device [10]. Combined with their standard-depth study of the actual construction of the library content of these heterogeneous databases, these heterogeneous data systematically cleaned to a unified coordinate system, unified administrative map, unified base map, unified geological bottom photo shows the basis for the conversion of spatial data. These databases are related to similar data dictionary table's entity name, domain, semantic standardization, to perform various special interactions, query analysis association.

Information fusion technology is proposed in the 1970s, which consists of a variety of information sources such as sensors, databases, knowledge bases and

humanity itself to obtain the relevant information and filtering [12], correlation and integration, thus forming an expressed frameworkб which is suitable to get information about decisions, explanation of the message to reach the target system, sensor management and system control. Information fusion is integrated multi-source information processing, with the nature of complexity. Signal processing and estimation theory indispensable for it's laid the theoretical foundation, which due to the high computational efficiency of the Kalman filter algorithm mature, etc., have been widely used.

Kalman filter based on minimum mean square error criterion for the best estimate, the basic idea is the use of state-space model of signal and noise, using the estimated value of the previous time and the current observation time updates on the status of the estimated variable, find the current the estimated value of the time [11, 13]. Assume that the discrete model for linear system:

$$x_k = F_k x_{k-1} + w_{k-1}, \tag{1}$$

$$z_k = H_k x_k + v_k, \tag{2}$$

where $v_k \sim N(0, R_k)$, $w_k \sim N(0, Q_k)$ are independent of each process, and $x_0 \sim N(x_0, P_0)$ independently in the initial state. Then for any loss function, the following Kalman filter equations:

The time update equations are given:

$$x_{t+1|t} = F_{t+1} x_{t|t}, \tag{3}$$

$$P_{t+1|t} = F_t P_{t|t} F_t^T + Q_{t+1}. \tag{4}$$

The measurement update equations are given:

$$K_{t+1} = P_{t+1|t} H_{t+1}^T (H_{t+1} P_{t+1|t} H_{t+1}^T + R_{t+1})^{-1}, \tag{5}$$

$$x_{t+1|t+1} = x_{t+1|t} + K_{t+1}(z_{k+1} - H_{k+1} x_{t+1|t+1}), \tag{6}$$

$$P_{t+1|t+1} = (1 - K_{t+1} H_{t+1}) P_{t+1|t}. \tag{7}$$

Kalman filter algorithm provides an effective way to filter out noise, is widely used to control, track, spacecraft orbit correction and other fields, has made many achievements. But the Kalman filter can only deal with the linear object, and the modernization of industrial production process the relationships among the variables are often very complex, using the linear model to reflect the relation between variables.

The Extended Kalman Filter (EKF) provides an online linearization method, namely the linearization of the nominal trajectory, and then uses Kalman filtering formula, which can solve the non-linear problem object to a certain extent. Set k time obtained system filtering system value is $x_{t-1|t-1}$ and $x_{t|t-1}$. The state equation is discrete systems in the vicinity of the $\hat{x}_{t-1|t-1}$ by Taylor series expansion, the linear model of the top two can have the original nonlinear system [8], it is given

$$\begin{cases} x_t = F_t x_{t-1} + U_{t-1} + \Gamma_{t-1} W_{t-1} \\ z_t = H_t x_t + Y_t + V_t \end{cases}, \tag{8}$$

where

$$F_t = \frac{\partial f(x_{t-1}, t-1)}{\partial x_{t-1}} | x_{t-1} = x_{t-1|t-1},$$

$$H_t = \frac{\partial h(x_{t-1}, t-1)}{\partial x_t} | x_t = x_{t|t-1},$$

$$U_{t-1} = f(x_{t-1|t-1}, t-1) - \frac{\partial f(x_{t-1}, t-1)}{\partial x_{t-1}} | x_{t-1} = x_{t-1|t-1},$$

$$Y_t = h(x_{t|t-1}, t) - \frac{\partial h(x_{t-1}, t-1)}{\partial x_t} | x_t = x_{t|t-1}.$$

By Kalman filter, EKF, UKF and other methods as well as other information fusion technology for large data processing, you can filter out the noise and easier to obtain the corresponding relationships between variables to improve the accuracy of analytical results.

4 Experiment and analysis

In order to test Yulin city groundwater monitoring data standardization process, we simulate multiple concurrent processing requests, validate the multitasking parallel speedup ratio and load balancing effect. Software and hardware environment test system is as follows. Hardware: X86-64 architecture server specific CPU (8 an 8 nuclear, frequency 2.6GHz), DDR3 32GB memory, SCSI hard disk (1TB, 10000rpm), Gigabit ethernet. Software: CentOS 5.2, Python 2.5.4, PostgreSQL 9.

1) Concurrent performance speedup test. At the start of single processing node A and dual processing nodes A, B, simulation 200 concurrent processing request, test and record the operation of each node respectively 1, 2, 3, 4, 5, 6, 7, 8 parallel processing example is complete when all tasks required processing time, finally the corresponding calculation speedup.

2) Load balancing test. Start the two processing node, A, B, each instance running 4 parallel processing, were recorded 20, 50, 200 systems, 260 processing tasks, each task number A, B node.

According to the concurrent performance speedup test scheme, processing and recording processing time, rendering acceleration as shown in Figure 4.

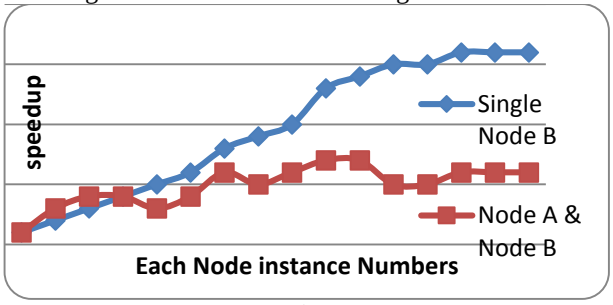

FIGURE 4 Concurrent performance speedup test result

From an overall perspective, both single node or double points, speedup ratio of parallel processing task instances with the growth in the number of approximate linear growth, with better performance of parallel processing system. With the parallel increase in the number of instances of processing tasks, accelerating gradually deviated from the theoretical speedup ratio, mainly due to an increase in instances of parallel processing with the internal system affect the communication time consuming and central control node and processing nodes for parallel processing speedup also gradually increased.

Testing according to the load balancing scheme, each node records the amount of processing to complete the task, the task of load balancing based on the drawing result of the number shown in Figure 5.

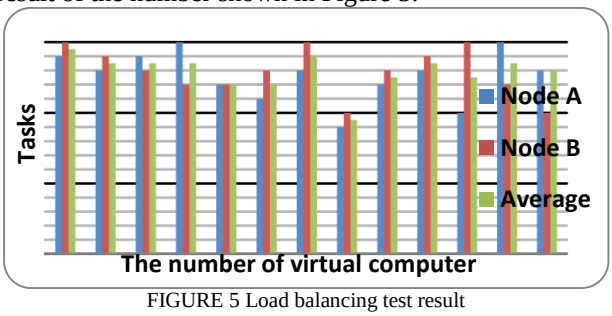

FIGURE 5 Load balancing test result

The test is repeated 15 times, the number of tasks handled similar to the average of each node, the total number of tasks as the load increases, the deviation gradually decreases, load balancing stability increase. Two node load quantity deviation, mainly because of the surplus is less than the number of instances of processing task concurrent processing, unable to realize the equalization processing, further processing resources or capability of instance share there are fluctuations and deviation.

5 Conclusions

This article has conducted the system research to the mine hydro geological spatial database and visualization of 3D geological modelling method, and created the data processing framework. From the perspective of water informatics starting to construct dynamic monitoring of groundwater resources groundwater model and a complete text of a large space method of data processing, thereby establishing groundwater regulation of technical methods and theoretical system of environmental, economic constraints, combined with groundwater regulation comprehensive integration platform implementation, and ultimately to create a unified UIPO models. In the model implementation, we have proposed a comprehensive cloud-based computing platform integration framework. Practice shows that this design is very suitable for implementing UIPO model.

Composition of web applications in clouds environment

Zuowen Wang*

School of Computer, Wuhan Polytechnic, Wuhan, 430074, China

Received 1 March 2014, www.cmnt.lv

Abstract

In recent years, for the advances of Cloud Computing technologies, cloud applications have been popularity for their rich set of features. The advantages of cloud applications include that users can utilize them in a low cost, threshold, and risk way; these applications can be quickly deployed on the clouds without duplication of work such that developers can focus on enhancing their QoS to improve core competitiveness. Therefore, their practical use on business with promising values can be expected. As such, cloud applications are recognized as a trend for the next generation of business applications, and hence how to migrate these on-premise applications to the clouds becomes a desired field in the literature. For this need, we present an ontology-based method for the composition process that specifically addresses the cloud features and the composition of on-premise applications into the clouds. In particular, for enabling the selection of desired clouds, the method imposes semantic ontologies on the specifications of the candidate clouds from which the desired ones can be effectively selected. For illustration, the method is applied to the composition of a CSS application to its cloud version.

Keywords: cloud computing, cloud application, semantic ontology, service composition

1 Introduction

Web service has already become an important paradigm for developing web applications. Growing number of web services raise the issue of efficiently locating the desired web services. Many approaches have been proposed with respect to the way in which services are described. Semantic communities provide ontology languages for web services such as OWL-s and WSMO. Services are organized in ontology. To locate desired services depends on semantic match of services. For the advances of Cloud Computing technologies in recent years, cloud applications have been popularity for their rich set of features. The advantages of cloud applications include that users can utilize them in a low cost-, threshold-, and risk-way; these applications can be quickly deployed on the clouds without duplication of work such that developers can focus on enhancing their QoS to improve core competitiveness. Therefore, their practical use on business with promising values can be expected. As such, cloud applications are recognized as a trend for the next generation of business applications.

In terms of the architecture for on-premise applications (e.g., web information systems), client-server patterns were most commonly used in the past decades; almost all kinds of existing on-premise applications were constructed using this style of architectures. However, as stated above, cloud applications have been recognized in recent years as applications to the clouds for taking advantage of cloud applications becomes a desired field in the literature. For this need, some discussions about the composition of on-premise applications into the clouds have been presented in [1-7]. In general, these statements have clarified some important issues about the composition and then proposed respective tips for addressing such issues. Thus, there are already many ideas about the cloud characteristics for composition; for instance, how on-premise applications are smoothly migrated to either of the three service models – SaaS, PaaS, and IaaS – supported in various cloud environments.

For the composition process, nonetheless, any methods that take into considerations of the architecture and characteristics of both on-premise applications and clouds to provide guidance on their composition are still missing. In addition, for the most critical issues in the composition process: the identification of candidate clouds and then the selection of desired ones from these candidates, few discussions can be found for addressing them by explicit formal approaches. Such methods and any formal approaches for addressing these critical issues, in our opinion, should not be negligible since a well-guided process and suitable formal issue approaches are most important for directing the composition of the many on-premise applications in a systematic and managed manner.

In this paper, we therefore present a method for directing the composition process. The method starts at the identification of the architecture and profile of the on-premise application to be migrated, through the discussion of the requirements for clouds and also the identification of the candidate clouds from which desired ones are selected with service models – SaaS or PaaS or IaaS – satisfying the cloud requirements, and finally ends

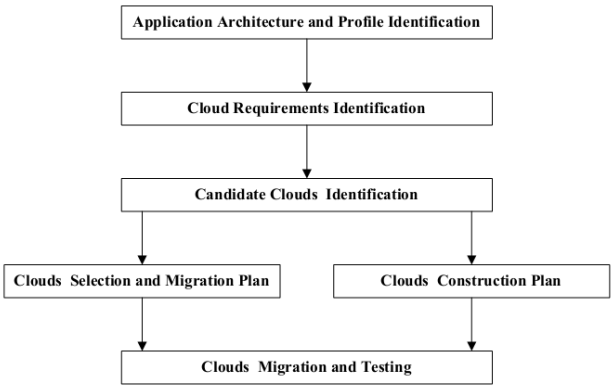

FIGURE 1 The Composition Method

at the deployment of the application on these selected clouds where a deployment and test plan is specified for conducting the deployment and tests. In particular, for enabling the selection of desired clouds, the method imposes semantic ontologies on the specifications of the candidate clouds such that desired clouds can be effectively selected by matching the desired cloud requirements with the provided services of these candidate clouds. Further, for addressing the exceptional situation that no candidate clouds can be found for smooth compositions, some discussions are also presented for conducting how on-premise applications may achieve their cloud-based versions via proper virtual mechanisms where either of the three service models – SaaS, PaaS, and IaaS – can be virtually supported in these mechanisms. For illustration, the method is applied to the composition of a Customer Support System (CSS) [8, 9] application to its cloud version that particularly emphasizes on both of collecting customer information (i.e., knowledge about/from customers) for enterprises and reversely delivering services information from enterprises to benefit customers.

This paper is organized as follows. Section 2 presents the composition method that encompasses three processes: an application-description process, a cloud-identification process, and an application- deployment process. The construction of semantic ontologies for enabling the selection of desired clouds is then presented in Section 3. For illustration, the method is applied in Section 4 to the composition of a CSS application to its cloud version. Finally, Section 5 has the conclusions and future work.

2 The composition method

As shown in Figure 1, the composition method has the following six steps:

1. Application Architecture and Profile Identification that determines (1) the architecture of the on-premise application where imposed components and their dependencies to support functional/non-functional purposes are specifically addressed; and (2) the profile of the on-premise application that includes the usage data about its executions (e.g., CPU, memory, storage, I/O, and network usage data) as well as the action data about its users (e.g., the number of active users, request rates, transaction rates, and request/transaction latencies).

2. Cloud Requirements Identification that clarifies the cloud requirements for the on-premise application based on its architecture and profile, including (1) for its components, the requirements for their deployment on the prospective services in clouds such as virtual machines, data storages, and a/synchronous message channels; and (2) for its usage and user actions, the requirements for their QoS in clouds such as customized user interfaces and access modes, performance, reliability, security, and scalability.

3. Candidate Clouds Identification that identifies the candidate clouds whose services (i.e., service models – SaaS or PaaS or IaaS – provided in clouds) satisfy the cloud requirements identified above. It is noticed that for the components of the on-premise application that have deployment requirements on clouds, there may necessarily have various clouds that collaboratively provide services to satisfy these requirements. Also, in particular, semantic ontologies are imposed on the specifications of these candidate clouds such that the services of these clouds are specified in an integrative and consistent manner.

4. Clouds Selection and Composition Plan that determines from the identified candidates which clouds will be selected for the composition of the on-premise application. As in above, since these candidate clouds are specified in integrative ontologies, the selection of desired ones from them can be effectively achieved by matching the desired cloud requirements with their provided services. After then, the plan about the activities and relevant artifacts involved in the composition into selected clouds will be specified. In general, the activities include (1) deploying the application components on the services in clouds; (2) deploying the interaction mechanisms among application components on the inter/intra-cloud interaction solutions over/in clouds; and (3) refactoring/restructuring deployed components for satisfying the usage and user actions requirements such as customized user interfaces and access modes, performance, reliability, security, and scalability.

5. Clouds Construction Plan that identifies and schedules the alternatives for the situation that no candidate clouds can be found for smooth compositions as stated above. In such a situation, the on-premise application may be considered to achieve its cloud-based version via virtual mechanisms where either of the three service models – SaaS, PaaS, and IaaS – can be virtually supported in these mechanisms.

6. Clouds Composition and Testing that realizes the composition of the on-premise application into selected or constructed clouds in accordance with the composition or construction plan identified above. As in usual, testing of the composition proceeds in accordance with the activities involved in the composition process. where the first step addresses an application-description process, the

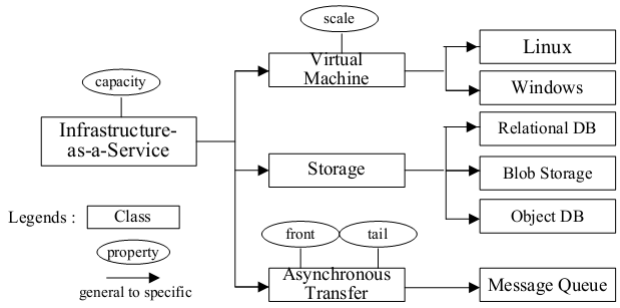

FIGURE 2 The hierarchy of classes for Infrastructure- as -a -Service

middle two encompass a cloud- identification process, and the last three cover an application-deployment process.

2.1 THE COMPOSITION METHOD

In this step, two descriptions about the on-premise application are addressed: (1) the architecture of the on-premise application; and (2) the profile of the on-premise application that includes the usage data about its executions as well as the action data about its users. For the architecture of the on-premise application, it specifically addresses desired architectural components with imposed behaviours and collaborations to support functional/non-functional purposes. As an example, the architecture of a Customer Support System (CSS) [8, 9] that emphasizes via the participant community [10-12] on both of collecting customer knowledge [13-16] for enterprises as well as reversely delivering services information to benefit customers: It is a 4-layer architecture of collaborative components where Customers interact with Enterprises via three intermediaries: Community, Customer Knowledge Agent, and Task Service Provider. It emphasizes on Community to help Customers share information about their desired tasks (e.g., buy or rent services from Enterprises). It emphasizes on collecting customer knowledge by Customer Knowledge Agent to help Enterprises catch their needs (e.g., provide services satisfying their desired tasks). It focuses on delivering services information by Task Service Provider from Enterprises to help Customers make recognition and comparisons.

With the architecture of the on-premise application, it is then good time to capture the profile of the on-premise application that can help size the application before it is migrated to the clouds. In general, the application data should be collected for at least 10 to 14 days to allow figuring out any variances in daily or weekly usage patterns. There are two kinds of data about the application: (1) the usage data about its executions (e.g., CPU, memory, storage, I/O, and network usage data); and (2) the action data about its users (e.g., the number of active users, request rates, transaction rates, and request/transaction latencies). With such application data, it is feasible to have an initial estimate of the cloud resources for the application to be migrated.

2.2 CLOUD REQUIREMENTS IDENTIFICATION

The second step is to identify cloud requirements for the on-premise application based on its architecture and profile, including (1) for its components, the requirements for their deployments on the prospective services in clouds such as virtual machines, data storages, and a/synchronous message channels; and (2) for its usage and user actions, the requirements for their QoS in clouds such as customized user interfaces and access modes, performance, reliability, security, and scalability. For the Customer Support System (CSS) as an example, its five components may require respective deployments on various cloud environments to support the functional/non-functional purposes via deployed clouds. Further, for its purposes of collecting customer knowledge for enterprises and delivering services information to benefit customers, it may require such QoS from these deployed clouds as customized user interfaces and access modes, performance, reliability, security, and scalability.

2.3 CANDIDATE CLOUDS IDENTIFICATION

The third step is to identify the candidate clouds whose services (i.e., service models – SaaS or PaaS or IaaS – provided in clouds) satisfy the cloud requirements identified above. For this, therefore, it is good to consider all of the cloud environments available on-line whose service models may satisfy the cloud requirements identified above. The following describes the possible service models in clouds:

1. Software-as-a-Service (Saas): In this model, the cloud provides application services, which may replace those provided by the on-premise application. With such SaaS services, many QoS features need to be evaluated for determining their replacement with the on-premise application as below.

(1) Their Service-Level-Agreements (SLAs) for availability, scalability, security, and performance; note that the evaluation for specific SLAs such as availability, scalability, and performance can be achieved by assessing the profile of the on-premise application.

(2) The compatibility of the application services with those offered by the SaaS.

(3) The portability of the application data into the SaaS for being accessed by the SaaS services.

(4) The portability of the access control by the application users into the SaaS for the access control by the SaaS users.

(5) The portability of the application interoperability with other services into the SaaS for the interoperable operations by SaaS services.

2. Platform-as-a-Service (Paas): In this model, the cloud provides platform services on which the on-premise application based on certain platforms such as JEE and MS.NET may be deployed under some QoS features as below.

(1) Their SLAs for availability, scalability, security, performance, and configuration (e.g., platform versions, APIs); note that as in SaaS, the evaluation for such SLAs as availability, scalability, and performance can be achieved by assessing the usage data about the application executions and the action data about the application users.

(2) The deployment of the application components and their interaction mechanisms on the PaaS for supporting the functional/non-functional purposes.

(3) The portability of the application services into the PaaS for the access by the deployed application users.

(4) The portability of the application data into the PaaS for being accessed by the deployed application.

(5) The portability of the access control on platforms (e.g., virtual servers) by the application users into the PaaS for the access control on clouds (e.g., virtual machines) by the deployed application users.

(6) The portability of the application interoperability with other services into the PaaS for the interoperable operations by the deployed application.

(7) The portability of the application management into the PaaS for monitoring and managing the deployed application.

3. Infrastructure-as-a-Service (Iaas): In this model, the cloud provides infrastructure services such servers, storages, and networks that the on-premise application and its deployed platforms may use under some QoS features as below.

(1) Their SLAs for availability, scalability, security, performance, and configuration; note that as in PaaS, the evaluation for such SLAs as availability, scalability, and performance can be achieved by assessing the profile of the on-premise application.

(2) The portability of the application services into the IaaS for the access by the deployed application users.

(3) The portability of the application data into the IaaS for being stored in the IaaS storages.

(4) The portability of the access control on infrastructure services (e.g., physical servers) by the application users into the IaaS for the access control on clouds (e.g., physical machines) by the deployed application users.

(5) The portability of the application interoperability with other services into the IaaS for the interoperable operations by the deployed application.

As a result, after considering all possible cloud environments that provide either of the above three service models, it is expected to identify some of them whose service models may satisfy the cloud requirements and then become the candidates to be selected for the realization of the composition. Since, as mentioned above, for enabling the selection of desired clouds from these candidates, semantic ontologies are imposed herein for the specifications of these candidate clouds such that the services of these clouds can be specified in an integrative and consistent manner. For the CSS as an example, Figure 2 shows the possible candidate clouds with service models that may satisfy the cloud requirements for the CSS.

2.4 CLOUDS SELECTION

The fourth step is to determine from the candidates identified above which clouds are selected for the composition of the on-premise application. As mentioned above, since these candidate clouds are specified in integrative ontologies, the selection of desired ones from them can be effectively determined by matching the desired cloud requirements with their provided services: (1) cloud requirements can be easily specified in terms of the structures and vocabularies of these ontologies, and (2) the matching of these requirements with the provided services of these candidate clouds can be easily undertaken. After determining the selection of targeted clouds, the plan about the activities and relevant artifacts involved in the composition into these selected clouds will then be specified. In general, the activities include (1) deploying the application components on the services in respective clouds; (2) deploying the interaction mechanisms among application components on the inter/intra-cloud interaction solutions over/in respective clouds; and (3) refactoring/restructuring any deployed components for satisfying the usage and user actions requirements such as customized user interfaces and access modes, performance, reliability, security, and scalability.

2.5 CLOUDS CONSTRUCTION

The fifth step is to identify and schedule the alternatives for the situation that no candidate clouds can be found at step 3 for smooth compositions. In such a situation, some alternatives may be considered; for instance, the on-premise application may be tailored to achieve a cloud-based version via specific virtual mechanisms [17-27] where either of the three service models – SaaS, PaaS, and IaaS – can be virtually provided through the support of these mechanisms.

The last step is to realize the composition of the on-premise application into selected or constructed clouds in accordance with the composition or construction plan identified above. As in usual, testing of the composition proceeds in accordance with the activities involved in the composition process.

3 Conclusion

In this paper, we present an ontology-based method for directing the composition of on-premise applications into selected clouds. The method takes into considerations of the architecture and characteristics of both on-premise applications and clouds to provide guidance on their composition. It therefore starts at the identification of the architecture and profile of the on-premise application to be migrated, through the discussion of the requirements

for clouds, the identification of the provided services of the available clouds, and the selection of the candidate clouds whose service models – SaaS or PaaS or IaaS – satisfy the cloud requirements, and finally ends at the deployment of the application into selected clouds where a deployment and test plan is specified for conducting the deployment and tests. In particular, for enabling the selection of desired clouds, the method imposes semantic ontologies on the specifications of the candidate clouds from which the desired ones can be effectively selected. For illustration, the method is applied to the composition of a CSS application to its cloud version that particularly emphasizes on both of collecting customer knowledge for enterprises and reversely delivering services information from enterprises to benefit customers. Since cloud applications have been recognized in recent years as a trend for the next generation of business applications, how to migrate the many existing on-premise applications to the clouds for taking advantage of cloud applications has thus become a desired field in the literature. However, current discussions about this need mainly focus on some important issues about the composition and then present respective tips for addressing such issues. For the composition process, any methods that take into considerations of the architecture and characteristics of both on-premise applications and clouds to provide guidance on their composition are still missing. Further, for the most critical issues in the composition process: the identification of candidate clouds and then the selection of desired ones from these candidates, few discussions can be found for addressing them by explicit formal approaches. Such methods and any formal approaches for addressing these critical issues, in our opinion, should not be negligible since a well-guided process and suitable formal issue approaches are most important for directing the composition of the many on-premise applications in a systematic and managed manner. The method and corresponding semantic ontologies presented herein provides an effort on this need.

As our future work, we will continue to explore the real composition of existing on-premise applications to the clouds where specific PaaS and IaaS offerings such as Google GAE and Amazon EC2 will be selected as the deployed or used platforms. As one may conceive, while migrating these applications, experiences about the composition can be collected correspondingly for validating the usefulness and effectiveness of the method. In fact, with our systematic and managed steps for gradually identifying and specifying application/cloud features and then conducting the deployment of the applications on the clouds, quality of these migrated applications on clouds can be expected.

OSTU image segmentation algorithm of fruit fly optimization algorithm

Chunyan Han*

Department of Computer Science, Sichuan University for Nationalities, Sichuan, 626001, China

Received 1 May 2014, www.cmnt.lv

Abstract

Traditional OSTU algorithm has the disadvantages of a large amount of calculation and low calculating speed. Based on the combination of Fruit Fly Optimization Algorithm and OSTU algorithm, an image segmentation algorithm is created from Fruit Fly Optimization Algorithm to improve OSTU, stressing the basic principles and calculation procedures of this revised algorithm. In order to verify the validity of this algorithm, the work compared the quality of image segmentation, segmentation speed and algorithm stability of 4 sets of standard test images. The simulation results show that the segmentation speed of revised OSTU algorithm is much faster than that of traditional OSTU algorithm when Fruit Fly Optimization Algorithm is applied to improve OSTU algorithm. Meanwhile, the quality of image segmentation is also more stable under the same condition of time limit.

Keywords: OSTU algorithm, image segmentation, Fruit Fly Optimization Algorithm, grey value, stability

1 Introduction

Image segmentation is the key technology of computer image visual processing. It has received extensive attention from researchers since it was proposed. So far, there are nearly one thousand kinds of image segmentation algorithm [1-3]. However, these algorithms are poor in versatility and are only applicable to some specific image segmentation issues rather than all images segmentations.

Based on the characteristics of large amount of calculation and low calculation speed of traditional OSTU algorithm, the work combined Fruit Fly Optimization Algorithm and OSTU algorithm and proposed an improved OSTU image segmentation algorithm by Fruit Fly Optimization Algorithm. Meanwhile, the work also compared the improved algorithm and OSTU, showing that both the segmentation quality and speed are superior to that of the traditional OSTU

2 OSTU method (also known as OSTU algorithm)

OSTU method is to set threshold value according to the sequence of grey value, and then classify images into 2 categories. Then, obtain the interclass variance through calculating the pixel and average grey-value of each category. In the end, set the threshold value as the final segmentation threshold when OTSU reaches its maximum. The calculation method of segmentation image is as follows [4-5]:

Classify the pixel of one digital image $f(x,y)$ into C_0 and C_1 by threshold T according to its grey levels. That is: $C_0 = \{f_1(x,y) \mid f_{\min} \le f(x,y) \le T\}$, $C_1 = \{f_2(x,y) \mid f_{\max} \ge f(x,y) > T\}$.

Here, $f_{\min}$ and $f_{\max}$ are respectively the minimum and maximum of the grey level of image $f(x,y)$. If N_i is set as the pixel when grey value is i ($f_{\min} \le i \le f_{\max}$), the total pixel of image $f(x,y)$ is $N = \sum N_i$. Therefore, the probability of the occurrence of each grey level is $P(i) = N_i / N$ and the total probability of the occurrence of C_0 is [6-7]: $P_0 = \sum_{i=f_{\min}}^{T} P(i)$.

Its mean value is: $\mu_0 = \sum_{i=T+1}^{T} iP(i) \Big/ P_0$.

The total probability of the occurrence of C_1 is: $P_1 = \sum_{i=T+1}^{f_{\max}} P(i)$.

Its mean value is: $\mu_1 = \sum_{i=T+1}^{f_{\max}} iP(i) \Big/ P_1$.

The mean value of image $f(x,y)$ is: $\mu = \sum_{i=f_{\min}}^{f_{\max}} iP(i) = \sum_{i=f_{\min}}^{T} iP(i) + \sum_{i=T+1}^{f_{\max}} iP(i) = P_0\mu_0 + P_1\mu_1$.

Define the interclass variance of the two categories is $\sigma^2(T)$: $\sigma^2 = P_0(\mu - \mu_0)^2 + P_1(\mu - \mu_1)^2$.

OSTU takes the interclass variances of the two categories as the determine evidence of selecting threshold value. It suggests that the best threshold value T^* should be the one when interclass variance $\sigma^2(T)$

* ***Corresponding author*** e-mail: han@scun.edu.cn

gets its maximum. That is: $T^* = \left\{ T^* \mid \sigma^2\left(T^*\right) \geq \sigma^2\left(T\right), \forall T \in \left[f_{\min}, f_{\max} \right] \right\}$.

3 Fruit fly optimization algorithm

3.1 OVERVIEW OF FRUIT FLY OPTIMIZATION ALGORITHM

Pan Wenchao [13], a young teacher in Taiwan, proposed Fruit Fly Optimization Algorithm (FOA), which is a new evolutionary calculation method. Fruit fly has the superiority on the senses of smell and visual, shown as Figure 1. Fruit fly can find food through searching the food sources in air, keenly locate food and its companions through its exquisite visual and finally fly to the food. Therefore, this method suggests that fruit fly usually determines an approximate position of food through its sense of smell and then locates the exact position of food through its sense of visual. This new method is for global optimization deduced from the action of fruit flies searching for food.

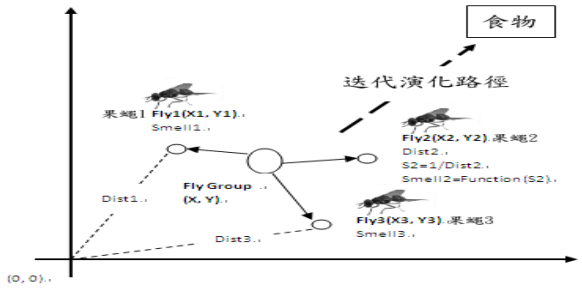

FIGURE 1 Fruit Flies Iteratively Search for Food

3.2 PROCEDURES OF FRUIT FLY OPTIMIZATION ALGORITHM

Fruit Fly Optimization Algorithm contains 7 steps. The specific procedure is as follows:

(1) As shown in Figure 1, initialize the location of fruit fly group and set the initialization results as $InitX\_axis$ s and $InitY\_axis$.

(2) When searching direction RV_x and RV_y are set, the stochastic searching distance of individual fruit fly can be obtained through the following formula:

$$Xi = Init\ X\_axis + RV_x,\ Yi = Init\ Y\_axis + RV_y. \quad (1)$$

(3) Estimate the distance $Disti$ between the current location of individual fruit fly and its original location because the location of food is unknown. Then, calculate the determination value of taste concentration S_i. Determination value of taste concentration equals the reciprocal of distance.

$$Disti = \sqrt{Xi^2 + Yi^2},\ Si = 1/Disti. \quad (2)$$

(4) Apply the determination value of taste concentration into determination function of taste concentration to calculate the taste concentration of this fruit fly at current location.

$$Smelli = Function(Si). \quad (3)$$

(5) The best taste concentration of fruit fly group can be calculated through the following formula:

$$[bestSmell\ bestIndex] = \max(Smelli). \quad (4)$$

(6) Keep the best taste concentration value of fruit fly group as well as its corresponding X coordinate and Y coordinate. At this time, fruit fly group can locate the food source according to their sense of visual and then fly to the food position.

$$\begin{aligned} &Smellbest = bestSmell, \\ &X\_axis = X(bestIndex), \\ &Y\_axis = Y(bestIndex). \end{aligned} \quad (5)$$

(7) Enter the iterative optimization step. Repeat iterative step (2) to (5) and determine whether the taste concentration is better than that of the previous iteration at the same time. If it is, then perform step (6).

4 USTO image segmentation of fruit fly optimization algorithm

4.1 DESCRIPTION OF THE ALGORITHM

When applying initialization, certain amount of fruit flies will be created at random. Calculate corresponding variance of the grey level of each fruit fly and find the maximum of variance among fruit flies. Then, update the location of fruit flies according to fruit flies optimization algorithm principles and procedures. When getting the set algebra, take the corresponding grey value of the maximum variance as the optimal threshold value to achieve image segmentation [8-9].

Specific procedure of the algorithm is as follows:

Step 1: Initializing the location of fruit flies and set the iteration times and the size of fruit fly group at the same time;

Step 2: Calculating the corresponding variance of the grey level of each fruit fly and compare the historical optimal value of individual and that of fruit fly group. Keep the location of current value and update the historical optimal value if the variance is superior to the historical optimal value of individual or fruit fly group; whereas, keep the current optical value;

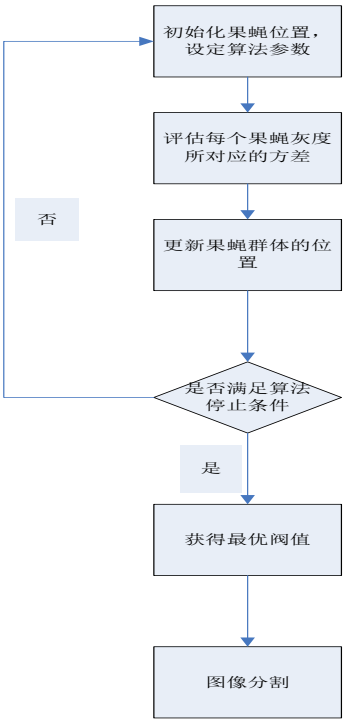
Step 3: Updating and changing the location of fruit fly according to the fitness value of fruit flies;

Step 4: If the iteration times $Iteration < Maxgen$, searching optimization completes; whereas, return to Step 2;

Step 5: Obtaining optimal threshold value and applying it to achieve image segmentation.

4.2 ALGORITHM FLOW CHART

The flow chart of Fruit Fly Optimization Algorithm improving OSTU algorithm is shown as Figure 2:



Initiate the location of fruit lies and set the parameter of the algorithm

Evaluate corresponding variancefor each grey value of fruit flies

Update the location of fruit fly group

Whether it meets the conditions to stop the calculation

Yes

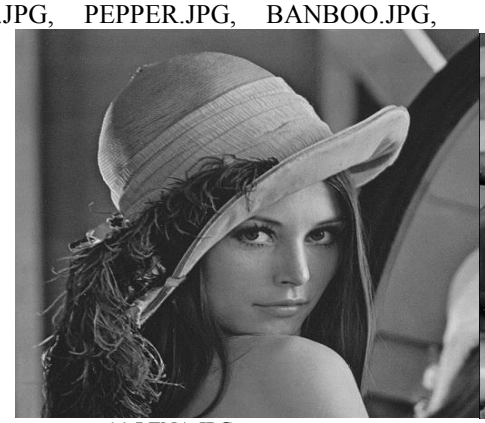
Obtain the optimal threshold value

Segment the images

FIGURE 2 OSTU Segmentation Method of Fruit Fly Optimization Algorithm

5 Algorithm test

Based on four standard images as test images [10-12], namely LENA.JPG, PEPPER.JPG, BANBOO.JPG, HUNTER.JPG, the work compared the segmentation effect of OSTU algorithm and FOAOSTU algorithm. The test images are shown as Figure 3:



(a) LENA.JPG

(b) PEPPER.JPG

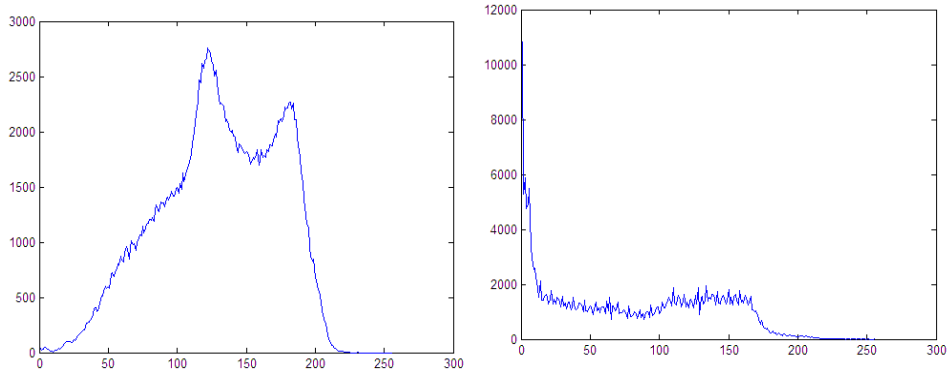
(b') PEPPER.JPG histogram

(c) BANBOO.JPG (d) HUNTER.JPG



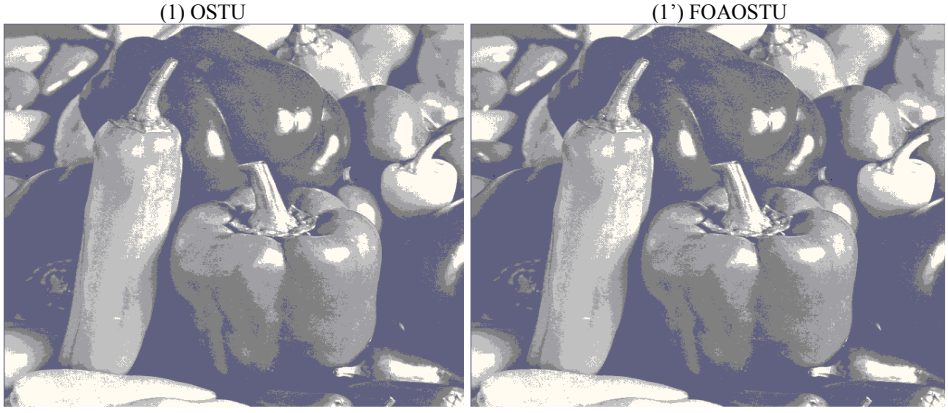
(c') BANBOO.JPG histogram (d') HUNTER.JPG histogram

FIGURE 3 Test Images and Corresponding Histogram

5.1 COMPARISON OF SEGMENTATION QUALITY

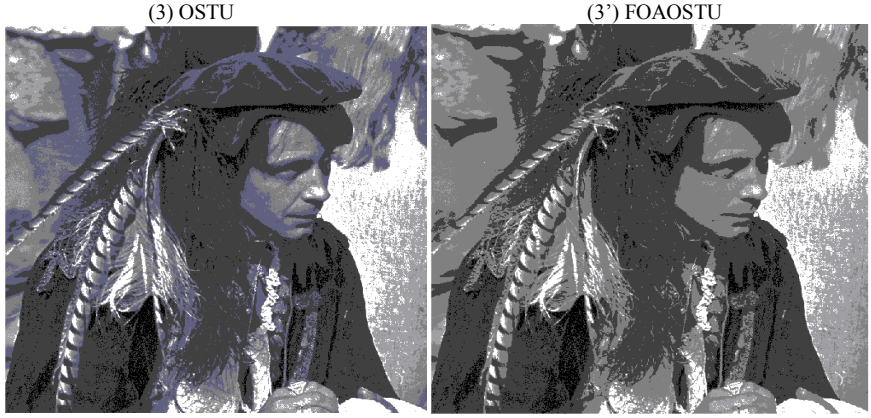
Figure 3 shows test images and the corresponding histograms. The segmentation comparison results of OSTU algorithm and improved OSTU algorithm by Fruit Fly Optimization are shown as Figure 4:

(1) OSTU (1') FOAOSTU



(2) OSTU (2') FOAOSTU

(3) OSTU (3') FOAOSTU



(4) OSTU (4') FOAOSTU

FIGURE 4 Comparison pictures of segmentation results of OSTU and FOAOSTU

Figure 4 shows that the segmentation of FOAOSTU algorithm is superior to that of OSTU algorithm, which ensures the segmentation speed and effect when achieving the edge information of images.

5.2 COMPARISON OF STABILITY

In order to compare the stability of OSTU algorithm and improved OSTU algorithm, the work applied formula (6) to evaluate the astringency [14-15] of the algorithm results:

$$std = \sqrt{\sum_{i=1}^{n} (\sigma - \tilde{\sigma}) / n} \,. \tag{6}$$

In the above formula, n refers to the times (set as 100 in the work) of repetitive computation of the algorithm; σ means the optimal solution obtained from every computation of the algorithm, and $\tilde{\sigma}$ refers to the average value of σ. Therefore, formula (6) is considered as the standard deviation of σ, which is labelled as std. Under the same condition, the bigger std is, the more unstable the algorithm is; whereas, it means the algorithm is more stable.

TABLE 1 Comparison results of the standard deviation of OSTU algorithm and FOAOSTU algorithm

Images	**Standard Deviation**	
	FOAOSTU	*OSTU*
LENNA	0.0912	6.8173
PEPPER	0.4738	3.3477
BANBOO	0.3015	5.3859
HUNTER	0.0968	3.9608

Table 1 shows that the stability of FOAOSTU algorithm is superior to that of OSTU algorithm, but its standard deviation is much smaller than that of OSTU algorithm.

5.3 COMPARISON OF SEGMENTATION SPEED

Table 2 shows that the segmentation speed of FOAOSTU algorithm is superior to that of OSTU algorithm, but its segmentation time is shorter than that of the OSTU algorithm.

TABLE 2 Comparison results of the segmentation speed of OSTU algorithm and FOAOSTU algorithm

Images	Segmentation Speed (Unit: Second)	
	FOAOSTU	*OSTU*
LENNA	0.32	0.75
PEPPER	0.38	0.67
BANBOO	0.43	0.82
HUNTER	0.56	0.79

6 Conclusions

According to the disadvantages of large amount of calculation and low calculation speed of traditional OSTU algorithm, the work applied fruit fly optimization algorithm to improve it and then segment images after obtaining optimal threshold value through this algorithm. The work carried out comparisons on image segmentation quality, segmentation speed and algorithm stability for 4 sets of standard test images. The simulation results show that when fruit fly optimization algorithm is applied to improve OSTU algorithm, and the segmentation speed of the improved algorithm is much faster than that of traditional OSTU algorithm. Meanwhile, the segmentation quality is also more stable under the same condition of time limit.

Colour recognition system based on TCS3200D

Lili Jing*, Yang Nie, Lifang Zhao

Jining Normal University, Inner Mongolia, 012000, China

Received 1 March 2014, www.cmnt.lv

Abstract

The colours of objects can be converted into pulses with different frequencies by TCS3200D. Colour recognition system was designed through the combination of Single Chip Microcomputer (SCM) and PC on the basis of the colour vision principle of TCS3200D. Fully utilizing TCS3200D, the system integrates the advantages of photodiodes and converter of light intensity to frequency to simplify circuit. The effects of factors, such as illuminant, orientation and the surfaces of objects, on the measurement were eliminated by the white balance adjustment. Additionally, colour vision errors were effectively reduced by the correction of the measured data with ANFIS and subtractive clustering.

Keywords: TCS3200D, colour recognition, ANFIS

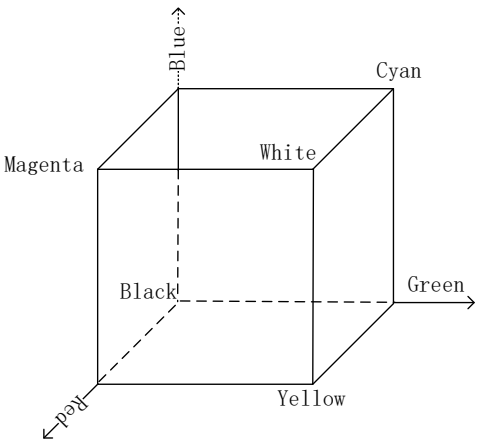
1 Introduction

As an important application, colour recognition has been widely used in various industrial detections. A separate photodiode is covered with the corrected red, green and blue filters in the typical colour sensor at present. Then, colour signal is recognized by the corresponding processing of the output signal. Some sensors combine two steps together to output analog signal. However, front channel processing, such as amplification, filtering and A/D conversion, should be conducted before computer processing in order to perform recognition. Consequently, the complexity of the circuit increases with a large recognition error, affecting the results [1]. Colour recognition is realized by TCS3200D made by TAOS (Texas Advanced Optoelectronic Solutions) Company. Square wave with a 50% duty cycle is directly produced by the conversion of light intensity to frequency of TCS3200D. Meanwhile, the output using the digital interface brings many new, excellent properties to TCS3200D.

2 Colour recognition principle of TCS3200D

2.1 RGB MODEL

The surface of object absorbs part coloured components in white light (sunlight) shining on it and reflects the other coloured parts to the eyes. Any colour can be obtained by the mixture of three primaries (red, green and blue) in different ratios. Three axes represent R, G and B in the RGB model of colour space (Figure 1). Origin corresponds with black (0, 0, 0), and the vertex farthest away from the origin white (255, 255, 255). The line connecting the origin with the farthest vertices represents grayscale distribution from black to white. The other six vertices of the cube represent red, yellow, green, cyan, blue and magenta, respectively. Each colour has a corresponding RGB value [2].



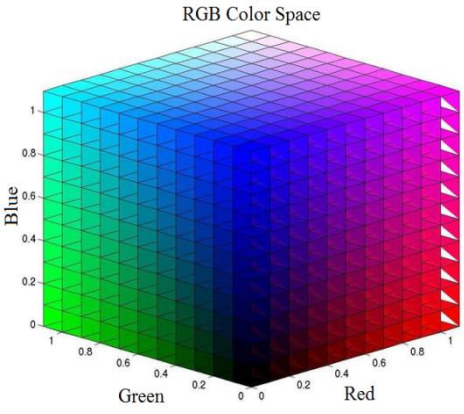


FIGURE 1 RGB model

***Corresponding author** e-mail: 15847418543@163.com

2.2 COLOUR RECOGNITION PROCESS OF TCS3200D

The colour of the tested object can be obtained with known RGB values according to the RGB model of colour space. TCS3002D only allows some particular colour to access but prevents the other colours after a colour filter is chosen. For example, only red incident light can access if red filter is chosen, while blue and green will be prevented. Then, the red light intensity can be measured. Similarly, the intensity of the blue or green light can be obtained if the other filters are chosen. RGB values are quantized by the linear conversion of light intensity to frequency signal. Then, the colour of the light projected to TCS3200D can be analysed.

The quantization process of RGB values is as follows. First, the RGB intensity value of reference light () was measured. Then, the intensity value $\left(P_{or}, P_{og}, P_{ob}\right)$ of light reflected by object was obtained under standard light. The ratio of two values was the reflection/transmission property of the object - the actual colour of the object (Equation 1).

$$K_r = P_{or} / P_{sr}, K_g = P_{og} / P_{sg}, K_b = P_{ob} / P_{sb}. \quad (1)$$

The standard coordinate of colour is among 0 to 255 in the RGB coordinate, so the standard RGB values were obtained by the result multiplied by 255.

2.3 WHITE BALANCE ADJUSTMENT

It should be noted that different light reflected by the object has different light intensities. Moreover, intensity components reflected by the object are different for non-standard white light (three unequal RGB values). Theoretically, white is composed by the same amount of red, green and blue. However, the amount of three primaries actually is not entirely equivalent in white. Equation (1) can be used to eliminate the effect [3]. The ratios are all 1 when an object is white. Therefore, the ratios multiplied by 255 were (255, 255, 255) —RGB values.

On the other hand, TCS3200D has different sensitivities to three primary colours, resulting in three unequal RGB values. The light intensity values $\left(P_{or}, P_{og}, P_{ob}\right)$ of three primary colours are not equal with the same induction time when TCS3200D is under white light. Therefore, white balance adjustment should be carried out before the test, adjusting the TCS3200D induction time of three primaries. For instance, induction time should be decreased with a higher sensitivity of red; otherwise the time should be increased. The induction time of three primary colours is determined as follows. First, the filters of three colours are sequentially gated, and then the output pulses of TCS3200D are counted. The time of pulses getting through each channel is calculated when the count is 255. The time is corresponding to the time standard used by each TCS3200D filter in actual tests. The numbers of pulses measured during the time are corresponding light intensity values - P_{or}, P_{og}, P_{ob} values.

3 TCS3200D

TCS3200D is the programmable converter proposed by TAOS Company of colourama to frequency. It integrates configurable silicon photodiode and a current-to-frequency converter on a single CMOS circuit. Moreover, three filters (red, green and blue (RGB)) are integrated on a single chip. Different combinations of pins S2 and S3 are controlled by photodiode, thus selecting different types of filters. Square waves with different frequencies (50% duty cycle) are outputted after current-to-frequency conversion with incident light projecting onto TCS3200D, corresponding to different colours and light intensities. TCS3200D can be directly connected to microprocessors or other logic circuits because the output signal with digital quantity can drives standard TTL or CMOS logic input. In addition, A/D conversion circuit is no longer needed because digital output can realize the conversion precision of more than 10 bit in each colour channel. Thus, the circuit becomes simpler. The pin and the function of TCS3200D are shown in Figure 2 [4].

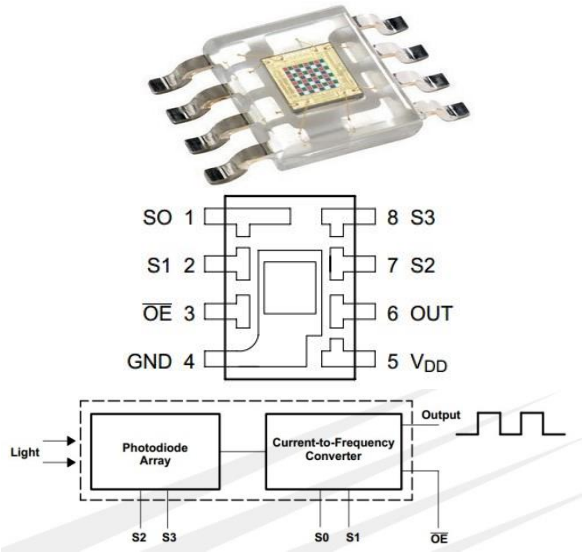

FIGURE 2 Pin and function of TCS3200D

TCS3200D (Figure 2) uses the 8-pin SOIC surface-mount package and integrates 64 photodiodes on a single chip. The photodiodes are classified into four types—16 with red filters, 16 with green filters, 16 with blue filters and the rest without filters (all optical information can access). The unevenness of the incident radiation is maximized through the stagger of these photodiodes in the chip, thus increasing the accuracy of colour recognition.

On the other side, the 16 multiple-connected photodiodes with the same colour are distributed evenly throughout the array to eliminate location bias among

colours. The typical range of output frequency is 2~500KHz. Users can choose the output scale factor (100%, 20% or 2%) or power down model *via* two programmable pins. The sensor output is applicable to different measurement ranges through the scale factor, improving its adaptability. For example, a small scaling value is selected to make the output frequency of TCS3200D match counter when low-frequency counter is used. The available combinations of S0, S1, S2 and S3 are shown in Table 1.

TABLE 1 Options of combinations

S0	S1	Output frequency scaling	S2	S3	Filter type
L	L	Power down	L	L	Red
L	H	2%	L	H	Blue
H	L	20%	H	L	Clear
H	H	100%	H	H	Green

4 Practical applications of TCS3200D

The hardware structure in this system adopted SCM application system and modular design. The principle block consists of LED module, colour recognition module, a microcontroller module and host computer module, as shown in Figure 3. Furthermore, display module, data storage module, operation module and serial communication module were included in the host computer module. The LED module improves the accuracy of colour recognition. The uniform arrangement along circle of four high-brightness, white LED makes the cross-section intensity of emitted beam evenly distributed, thus obtaining better recognition effect.

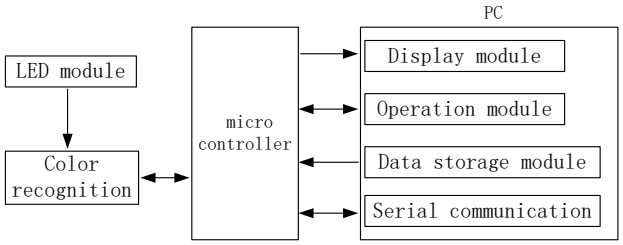

FIGURE 3 Connection between TCS3200D and Microcontroller

Microcontroller was connected to TCS3200D through SCM STC89C51 (Figure 4). First, TCS3200D driver determined whether white balance was need, and then the TCS3200D filters were gated successively. Subsequently, the timing was performed on the basis of the time standard in white balance adjustment. Meanwhile, the number of TCS3200D output pulses was counted. Finally, the results were transmitted to the PC through the serial port.

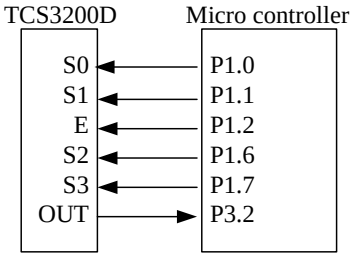

FIGURE 4 Connection between TCS3200D and Microcontroller

5 Colour vision optimization with ANFIS and subtractive clustering

The colour sensor and hardware circuit design can cause some systematic deviations of system measurement, which cannot be described with existing physical knowledge. There is an unknown nonlinear relationship between the output value and the actual value of sensor. With strong nonlinear approximation ability, ANFIS (Adaptive-Network-based Fuzzy Inference System) is entirely feasible to the non-linear calibration of sensor. Therefore, the calibration model based on ANFIS and subtractive clustering was adopted for the correction of the values measured by colour sensor.

First, samples were obtained by calibration experiment. Then, ANFIS network structure was determined by subtractive clustering. Subsequently, the system was trained with hybrid learning algorithm. Finally, the trained system was applied to the characteristic correction of sensor. The correction process is shown in Figure 5 and Figure 6 [5].

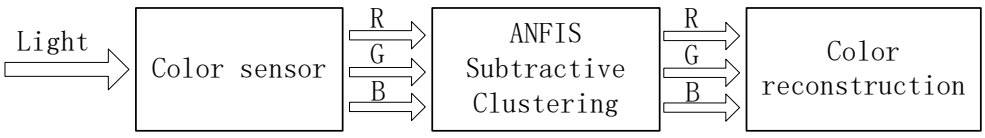

FIGURE 5 Optimization of colour sensor's output

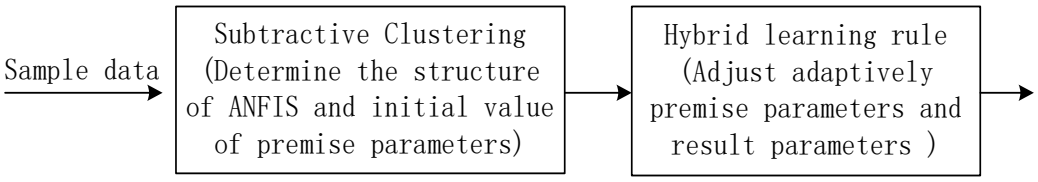

FIGURE 6 Process of designing ANFIS

Each output corresponds to a three-input and single-output ANFIS system (Figure 5). It should be noted that calibration points cannot be arbitrarily selected for training samples, while sample data should be selected on the basis of certain law. Thus, the data are representative so that correction model ANFIS is finally obtained with higher accuracy and universal applicability. The more the selected samples are, the better the correction effect of the model on results will be. Varying among 0-255, RGB selected the values of five specific points—0, 64, 128, 192 and 255. There are a total of 125 sample data, used to build correction model ANFIS [6].

ANFIS was used to compensate the sensor output as follows:

1) The related training and test samples were obtained.

2) The fuzzy rules of ANFIS and the initial values of parameters were determined using subtractive clustering according to training samples.

3) ANFIS training was conducted, and its performance was judged using test samples. If the performance was not good, then the evaluation threshold of clustering centre should be modified in the clustering algorithm. Thus, the number of ANFIS fuzzy rules was changed until ideal correction results were obtained.

4) The sensor output of actual colour was corrected using ANFIS trained well.

The data sent by the SCM through serial were processed using VISUAL C++ programming at the PC-terminal. The colour vision results, optimized using ANFIS and subtractive clustering, are shown in Figure 7. As can be seen from Figure 7, the RGB values after recognition are very close to those of recognized colour. Therefore, the effect of colour vision is excellent.

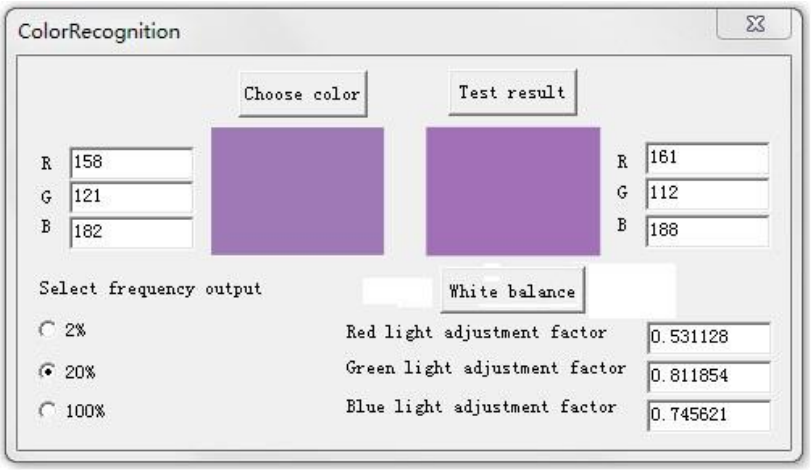

FIGURE 7 TCS3200D colour vision results

In addition, the following questions should be noted in the TCS3200D application:

1) Colour recognition is susceptible to interference from the external environment, e.g., stray light, etc., will affect the accuracy of colour recognition. Therefore, LED lighting system, the object to be tested and colour sensor were placed in the shading light cylinder in the design of system structure. Then, the effect of light from the outside world can be avoided during colour measurement to reduce measurement errors.

2) White balance adjustment is necessary for the first use of TCS3200D, reboot, replacement of lighting source, etc.

6 Conclusions

Light, observation orientation and surface of measured object and other factors have important effects on measurement results, which is the difficulty in colour measurement. The colour vision principle of TCS3200D was analysed, and its characteristics, such as high integration and digital output interface, were fully used. The output data of sensor was collected through SCM STC89C51, avoiding complex circuit processing. LED light effectively eliminates the effect of light instability on measurement. Client was designed through VC++ at the PC-terminal. Moreover, ANFIS and subtractive clustering were used to optimize the results of colour vision, thus greatly reducing measurement error. TCS3200D can be widely used in various industries where the measurement, analysis and recognition of light colour components are required.

Distributed ontology based information retrieval using semantic web

Chun Zhang*

Shantou Radio and TV University, Shantou, Guangdong, 515041, China

Received 1 March 2014, www.cmnt.lv

Abstract

In recent years, user demand for integrated searches over several independently operating semantic web systems have been increasing rapidly. Integrated semantic searches enable more meaningful results to be generated because information with similar meanings in diverse areas and domains is likely to be used for inference. However, it is not easy to integrate physically independent, distributed, and heterogeneous database systems to provide a single, integrated semantic web system to end-users. In this paper, we propose a novel system that integrates heterogeneous semantic web systems based on schema mapping. The user can generate only one SPARQL query using the integrated schema without the necessity of checking the schemas of individual systems each time thereby reducing additional costs to generate queries for individual systems. Furthermore, the user is not required to collect individual query results manually after performing a query and additional costs for establishing systems can be reduced because no change in existing system structures is required. If currently established systems are expanded by adding the schema structures of other ontology systems, the cost to establish another integrated retrieval system can be saved. To evaluate the effectiveness of our approach, we have implemented a prototype that integrates two national information retrieval systems.

Keywords: integrated information retrieval, ontology, schema mapping, semantic web

1 Introduction

As the semantic search has been positioned as a killer service, many conventional information retrieval systems have been transformed into semantic web systems. In the early days, individual semantic web systems were built based on their own requirements and operated independently. As a result, users of a particular semantic web system were presented with the information managed only by the system. More recently, user demands for integrated searches over several independently operating semantic web systems have been increasing rapidly. This has occurred because integrated semantic searches enable more meaningful results to be generated, as information having similar meanings in diverse areas and domains is likely to be used for inference. However, it is not an easy task to integrate physically independent, distributed, and heterogeneous database systems to provide a single, integrated semantic web system to end-users. For physical integration, existing legacy data from participating systems must be transformed according to the integrated schema and whenever new data are accumulated in the participating systems, the transformation process must be repeated.

The Semantic Web [10-13] is a collaborative movement led by the international standards body, the World Wide Web Consortium (W3C). The standard promotes common data formats on the World Wide Web. By encouraging the inclusion of semantic content in web pages, the Semantic Web aims at converting the current web dominated by unstructured and semi-structured documents into a "web of data". The semantic web technology can be used in the pattern recognition layer. For example, with the help of the specific domain ontologies, the objects and relations of videos can be detected accurately.

A semantic link network (SLN) [14-17] is a relational network consisting of the following main parts: a set of semantic nodes, a set of semantic links between the nodes, and a semantic space. Semantic nodes can be anything. The semantic link between nodes is regulated by the attributes of nodes or generated by interactions between nodes. The semantic space includes a classification hierarchy of concepts and a set of rules for reasoning and inferring semantic links, for influence nodes and links, for networking, and for evolving the network. The semantic link network can be used in the video resources layer [18-20]. For example, with the help of the semantic link network model, the videos can be organized with their semantic relations.

In this paper, we propose a novel system that integrates heterogeneous semantic web systems based on schema mapping. The proposed system works by first creating integrated schema that includes all the attributes of the ontology schemas of participating semantic web systems (e.g., local schema). In the process, it maintains schema-mapping information that indicates which attribute of the local schema corresponds to that of the integrated schema. Second, user queries are generated against the integrated schema. Third, for query execution, the system re-

***Corresponding author** e-mail: cronychun@vip.qq.com

generates actual queries from the original user query in such a way that the attributes of the integrated schema are replaced with the corresponding attributes of the local ontology schema of the individual semantic web systems using the schema-mapping information. The core concept of the above-mentioned process is depicted in Figure 1.

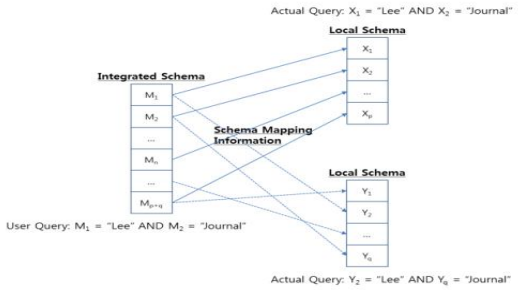

FIGURE 1 The schema mapping and query regeneration concept

To evaluate the effectiveness of our approach, we have implemented a prototype that integrates two national information retrieval systems, the National Discovery of Science Leader (NDSL) and the National Science and Technology Information Service (NTIS). The NDSL is an online database retrieval system that began service in 1962; it retains more than one hundred million pieces of information regarding research papers and reports, patents, standards, factual information, etc. The NTIS was developed in 2008 to enhance R&D investment efficiency by sharing and jointly utilizing information related to national R&D projects and science technology that are managed separately by individual government departments. Approximately 3.5 million pieces of data have been accumulated in the NTIS including national R&D and evaluation committee members, project information, result information, and research equipment information. Since the NDSL maintains only those pieces of information contained in journals, it does not retain information on what research projects‟ outcome the papers contained in the journals are. On the other hand, the NTIS does contain information about papers and reports for the outcomes of R&D projects carried out since 2008. Therefore, if the NDSL and the NTIS were linked to perform integrated retrieval, the value and the reliability of information from the two systems could be enhanced to be complementary.

The organization of this paper is as follows. Section 2 presents related work and Section 3 describes the proposed system architecture in detail. Section 4 presents classification of integrated queries and methods for sub-query generation. Section 5 presents experimental results. Finally, Section 6 provides a summary and proposals for future work.

2 Related works

Similar to ours, the ISENS [1] system provides a function to integrate and retrieve different real-world data sources having different ontologies. This system is less useful because queries in this system cannot be answered independently using a single system; instead, integrated queries can be made only to systems composed of mutually complementary data. In [1], mapping information for ontology schemas was not gathered in one place, but instead was made only for two ontologies with fields that can be mapped. Therefore, the existence of mapping information cannot be known without accessing the source system, which means that the mapping information can be accessed only through navigation. The largest difference between the present paper and [1] is that, instead of creating queries appropriate for individual local sites using mapping information, performing the queries, and integrating the results, in the case of [1]. The same query is performed using mapping information, the next system is accessed using the KAON2 reasoner to collect information, and results are presented but each database system cannot be accessed without using the system's source description and the source selection algorithm.

The DARQ system in [3] is also intended to perform integrated retrieval for distributed systems. However, this study is quite different from the study set forth in the present paper. In the DARQ system, heterogeneous data should be accessed using wrappers and the service description describes the kinds of data and access patterns that can be used for individual sites (endpoint) using sets of predicates. The DARQ system is different from the system in the present paper in that it focuses on query optimization using statistical information for integrated retrieval.

The SECO system in [2] enables efficient collection of any RDF files existing on the Web and provides interfaces in the form of HTML so that users can easily identify integrated data. This system is composed of a collector, a wrapper, a transformer, a user interface, a remote query interface, and data storage. The data storage is composed of multiple different sets of RDF data. Among them, MetaModel has Metadata information collected from files. SourceModel stores original RDF triples collected from files existing on the web and triples created here are purified through the transformer and stored in the TargetModel thereafter. The TargetModel enables access to user interface for creating HTML and remote query interfaces for query processing. The MetaModel, the UsageModel, and the TargetModel are described as ontologies and the SourceModel is composed of diverse schemas without any particular form.

3 The proposed architecture

Figure 2 depicts the overall architecture of the proposed system. The primary components of the system are the Schema Manager, the Query Manager, and the Result Manager. In what follows, we present detailed information about each component.

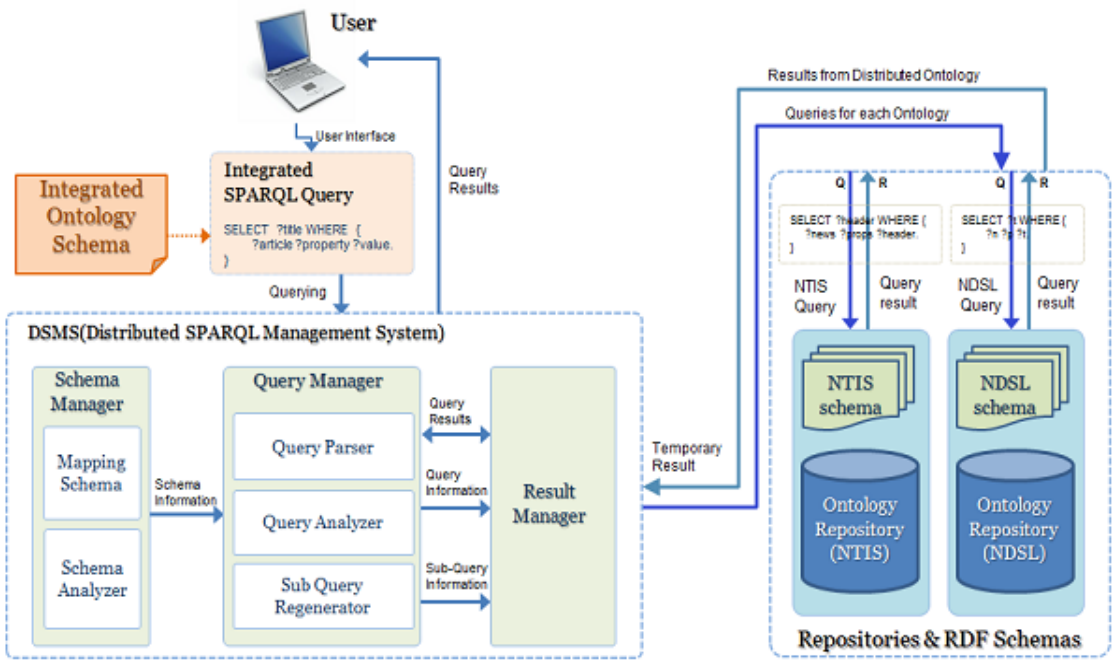

FIGURE 2 The system architecture

The NDSL and the NTIS define their own ontology schemas. Using the individual schemas, the administrator connects classes and attributes having the same meaning but different names with each other to create integrated schema that can link and retrieve two ontologies together. Therefore, the Schema Manager must maintain the Resource Description Framework (RDF) schema created by the administrator, as well as RDF schemas for individual ontologies of the NDSL and the NTIS. Both the NDSL and the NTIS have information on papers and the authors of the papers in common but they represent the information in different ways. For example, the People class in the NDSL schema and the Person class in the NTIS schema both indicate a human, but they are expressed differently. In contrast, both the NDSL and the NTIS schemas have a Journal class to represent a journal. Among the attributes defined in the classes, korName, hasName, write, and hasFirstAuthor are the attributes with the same meanings in both schemas. Therefore, the primary role of the Schema Manager is to maintain information about how individual classes and attributes defined in one schema are mapped to those defined in another schema. Note that classes and attributes in the integrated schema contain the level information, which is the core information needed by the sub-query generator. For example, classes such as Paper and Project are assigned to level 1, while hasFirstAuthor and korName attributes are assigned to level 2 and level 3, respectively. The level is related to the linkage of the class or the attribute. For instance, the hasFirstAuthor attribute has the identifier of the author but it does not have the name of the author. To acquire the author name, another triple condition such as ID :korName authorName must be executed. Therefore, the levels are constructed using the concept of linkage. How the level information is utilized will be described in the next section. The Schema Analyser analyses the schema information in the single SPARQL query submitted by the users. Then, it compares it with the RDF schemas of individual ontologies. Next, it delivers the information of the corresponding ontologies to the Query Manager.

The user creates queries based on integrated schema regardless of whether the ontologies managed by different information retrieval systems exist. The user query is first analysed using individual ontology schemas and the mapping schema. Subsequently, sub-queries are generated that are suitable for the corresponding ontologies. The Query Manager consists of the query parser, the query analyser, and the sub-query generator. When the query is verified by the query parser, the type of the query is determined through the query analyser. Using the integrated schema created by the administrator, the query parser checks the validity of the class and the attributes in the query. Then, using the schemas of individual ontologies, the query analyser determines whether the user query can be transformed into sub-queries for individual ontologies. Finally, the sub-query generator re-generates sub-queries. The sub-query generator and the query type will be dealt with in detail in the next section.

The Result Manager manipulates the intermediate results obtained by performing sub-queries in individual ontology for further processing or preparation for the final results. For example, depending on the query type, the Results Manager uses the results from one sub-query as filter information for another sub-query or it combines the results of sub-queries for the final query result.

4 Query generation

The query types determined by the query analyser are automatically generated into four types depending on the content of the information that the integrated query will retrieve. Type-1 queries represent those queries using the schema that exist only in one ontology. The integrate query includes the „Project" class, which exists only in the NTIS schema. Therefore, there is no corresponding sub-query for the NDSL. Figure 3 shows the control and data flows for processing the Type queries.

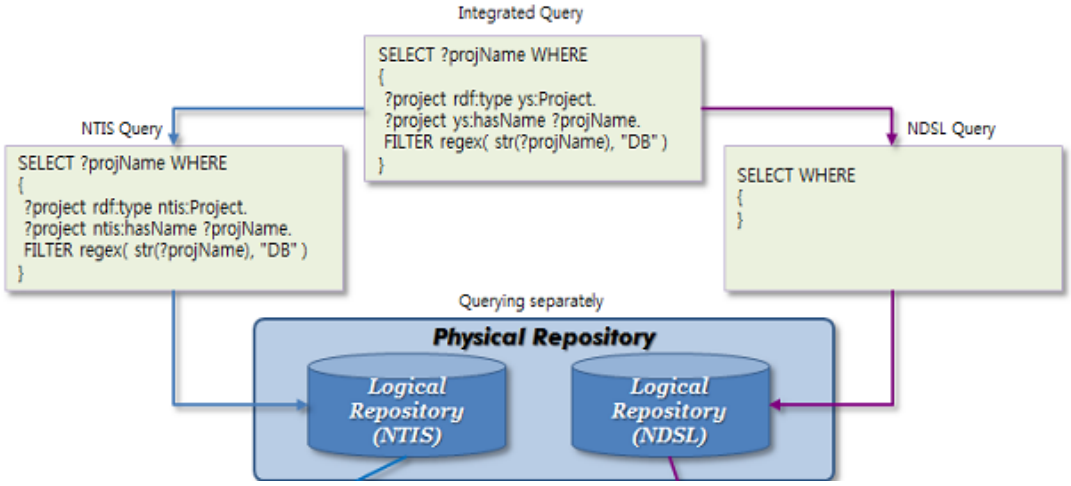

FIGURE 3 Control and data flows for processing Type-1 queries

Type-2 queries include classes and attributes that exist in every ontology. When retrieved using classes and attributes such as Paper and Author that the NDSL and the NTIS have in common, the query result is in the form of a combination of individual sub-query results. Figure 4 shows control and data flows for processing Type-2 queries. In Type-3 and Type-4 queries, some of the classes and attributes included in the queries exist in every ontologies, but the other classes and attributes are defined only in one ontology. For instance, the „Author" attribute exists both in the NDSL and in the NTIS schemas, whereas the Project attributes exists only in the NTIS schema. When queries are received of these types, the sub-query generator first separates the commonly existing classes and attributes from those that exist individually. For those classes and attributes that exist in only one ontology, they will be eliminated from the sub-queries for the ontologies that do not support them.

The example for a Type-3 query is "papers written by those who participated in the project for establishment of a driving safety DB and development of operating technology".

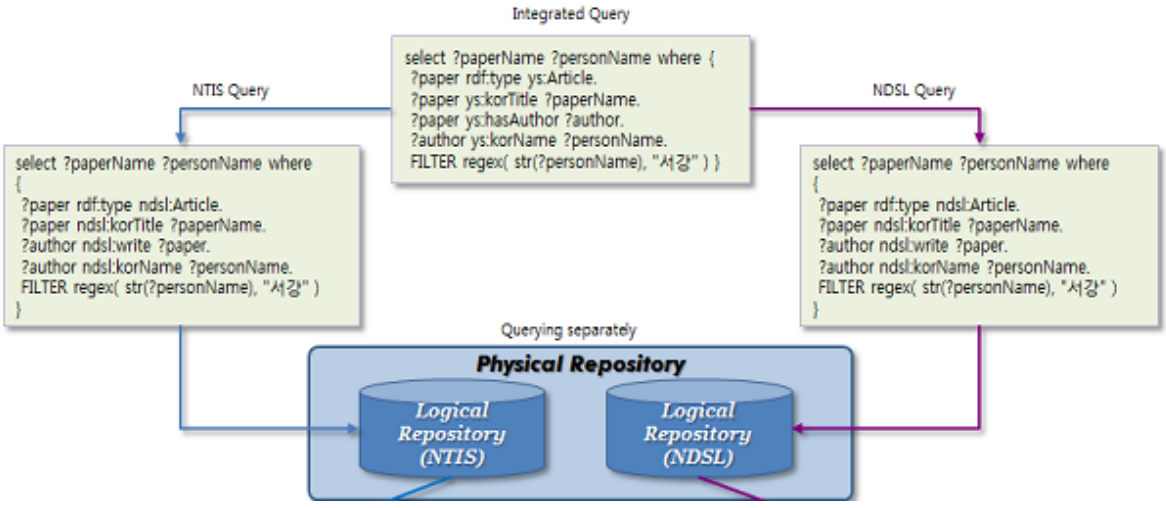

FIGURE 4 Control and data flows for processing Type-2 queries

The Figure 4 Control and data flows for processing Type-2 queries example for a Type-4 query is "projects in which the author of the paper „Diesel Engine participated". Project and participateIn in the integrated query do not

appear in the sub-query for the NDSL because the relevant classes and attributes do not exist in the NDSL schema. In the sub-query for the NTIS, the class Article is transformed into Paper and the attribute korTitle is transformed into hasName.

Type-3 and Type-4 queries have similar basic preconditions but differ from internal processing. For Type-3 queries, intermediate query results are first obtained by using classes and attributes that exist exclusively in one ontology. Then the commonly existing classes and attributes are applied to the intermediate query results. On the other hand, Type-4 queries apply query results obtained using common classes and attributes to queries for exclusive classes and attributes in a certain ontology.

To process Type-3 queries, given the two ontologies A and B, a query that includes the schema for A must be executed first. A query for B is also generated up to the WHERE clause excluding the FILTER clause. The FILTER clause to be included in the query for B will be generated by analyzing the intermediate query results from A and the queries for A and B (The query for A is complete, whereas the query for B is incomplete). First, all attributes that exist exclusively in the schema for A are extracted. Then, they are compared with the schema for B and the intersection of the two in the lowest level. Finally, the intersection and query results obtained from A are compared to generate the FILTER clause and complete the query for B. For instance, a Project exists in the NTIS schema and its level is one. The „Project" has participant for level two. The participant has a participantName, which is level three. The participantName is matched with authorName of Author of Paper in the NDSL schema. The FILTER clause is completed through these traces. For Type-4 queries, the FILTER clause is generated similarly to Type-3 queries. However, it is different from Type-3 queries in that the query results for individual ontologies extracted using classes and attributes that commonly exist in A and B. The results are then used to generate a FILTER clause for classes and attributes that exist exclusively in A or B.

5 Experiment and results

For each query type, we generated ten queries automatically and measured the performance of the proposed system in terms of the number of retrieved tuples and processing time. NDSL query results are not indicated because the integrate queries use only classes and attributes that exist exclusively in the NTIS schema. Sub-queries are generated for individual ontologies and the results are brought and integrated. In this case, the sum of the two query results differ slightly because overlapping values exist in the two query results, and they are treated as a single value.

NTIS query results are the same as the integrated query results. This indicates that the results obtained from the NDSL did not greatly affect obtaining the results from the NTIS. In other words, in the case of projects in which the author of a certain paper has participated", the author of the particular paper in the NDSL had hardly participated in NTIS projects or he participated in some cases but the cases were removed as overlapping results. This can be considered an issue of the scope and diversity of the data existent in each ontology. Queries for individual ontologies were not processed in parallel with each other because there are cases where the result values of queries for one ontology are included in the conditional clauses of queries for the other ontology. Although the results of individual queries were brought from ontologies, the integration of the results and the removal of overlapping results were made by the Result Manager using the memory of the relevant system. On reviewing individual experimental results, it can be seen that the time spent for integration is not something about which to be greatly considered.

6 Conclusions

In this paper, we proposed a novel system that will enable storing data from two different ontology systems in one physical system without converting the data to conduct integrated retrieval. Based on the individual schemas of the separated systems, the administrator can connect the schemas that have the same meanings but different forms of expression with each other between the two systems to generate integrated schemas. The user can then generate integrated SPARQL queries utilizing the schemas generated by the administrator to perform queries without recognizing the existence of individual ontologies. The user can generate only one SPARQL query using the integrated schema without the necessity of checking the schemas of the individual systems every time thereby reducing additional costs to generate queries for individual systems. Furthermore, the user is not required to collect individual query results manually after performing a query and additional costs for establishing systems can be reduced because no change in existing system structures is required. If currently established systems are expanded by adding the schema structures of other ontology systems, the cost to establish another integrated retrieval system can be saved. Although the complexity of applications will increase in this case, it should be a trivia l problem compared to the cost to integrate several millions or several dozen millions of triples manually.

In the future, the performance of result integration algorithms should be improved by adding more triple data and more query types should be added. If the system is complemented by establishing multiple ontologies in completely distributed network environments instead of a single physical storage, a more reliable system can be implemented.

Research on cost-sensitive ensemble classification for mining imbalanced massive data streams

Yuwen Huang[1, 2*]

[1]*Department of Computer and Information Engineering, Heze University, Heze 274015, Shandong, China*

[2]*Key Laboratory of computer Information Processing, Heze University, Heze 274015, Shandong, China*

Abstract

The existing classifiers for massive data streams do not consider the imbalance distribution and cost factors, so this paper proposes the approach of the cost-sensitive ensemble classification for imbalanced massive data streams (CECIDS). Firstly, this paper gives the construction method for cost-sensitive ensemble SVM Classification, which is integrated by the classifiers with oversampling, sub-sampling and reconstituted sample space. Secondly, we propose a classifier method BL_KNNModel, which is based on KNNModel algorithm for imbalanced massive data streams. BL_KNNModel can detect the concept drift streams by using the variable windows size, which has lower time complexity. At last, the cost-sensitive ensemble classifier for imbalanced massive data streams is given, which has the virtue of high classification and lower time complexity. In addition, the cost-sensitive ensemble SVM algorithm is used to handle the confused instances. The experiments using both synthetic and real datasets show that compared to the other classification algorithms for imbalanced data streams, CECIDS has higher evaluating indicator and more excellence integrated learning curve.

Keywords: Imbalanced data streams, Ensemble classification, Cost-sensitive SVM

1 Introduction

In recent years, with the development of computer techniques, more and more massive data Streams are produced in wireless sensor networks, network traffic monitoring, credit card fraud detection, earthquake monitoring and weather forecast. The traditional data mining methods are designed on static data, and massive data streams are real-time and dynamic variability, so the traditional data mining techniques can not effectively handle massive data and the research for massive data streams is the hot spot in mining data. The current model for massive data streams can be classified into two categories, one is the single-model structure, and the other is multi-model. A model structure is used to classify the data flow in single-model structure, and the common classification models are as follows. Abdulsalam proposed a method to use incremental learning for data stream classification, which can accelerate self-renewal by the incremental processing model [1]. Hashemi designed a complete data stream processing classification method, which is called the flexible decision tree model [2]. Tang proposed SVM model for unbalanced data stream classification [3]. Kuncheva proposed a data stream classification variable model with sliding window, which can automatically enlarge and reduce the size of the window when the concept drifts occur [4]. Liang extended the very fast decision tree algorithm for handling no labels data [5]. The integrated classification models for massive data streams use multiple identical and different classification models with the hybrid architecture to build strong classifiers. Amin was inspired by thoughts of the integrated learning, and used multiple single-layer neural networks to build an integrated learning model [6]. Avci proposed a mixed method based on the genetic algorithm and support vector machine model [7]. Bu built the hybrid learning model to use Bayesian networks and probabilistic neural network combination by the context of human motional data stream [8]. Chen proposed a mixed element based on Meta-evolution rules respond classification model [9]. Chi proposed an integrated learning ideological classification model based the hyper spectral remote sensing data stream [10]. Dembczynski built integrated learning classification model for the multi-standard problem to use the monotonic constraint method [11]. Hashemi built an integrated multi-decision tree classification model by a hybrid approach [12]. Huang used the ant colony optimization algorithm and support vector machine model to build an integrated classification model [13]. Adler used the bootstrap method by extracting different training set to build an integrated learning model [14]. Baumgartner and Serpen proposed a heuristic classification hybrid model [15]. The distributions of massive data streams in practical applications in are unbalanced, and the numbers of certain classes are less than other classes, which are called imbalanced massive data stream. There are little researches on imbalanced data stream classification. Gao proposed an ensemble classification model by oversampling for imbalanced data streams [16]. Adel proposed cost-sensitive neural network for imbalanced

* ***Corresponding author*** e-mail: 57065873@qq.com

data streams [17]. Liu gave algorithm of reusing data for classifying skewed data stream [18]. GAO proposed an approach for classifying data with imbalanced class distributions and concept drifts [19]. By improving KNNModel algorithm and constructing cost-sensitive ensemble SVM Classification, this paper proposes the approach of the cost-sensitive ensemble classification for imbalanced massive data streams.

2 Cost-sensitive ensemble SVM classification

2.1 COST-SENSITIVE SVM CLASSIFICATION

The goal of traditional SVM minimizes the objective function, and the linear inseparable is as follows.

$$R(w,\xi)=\frac{1}{2}\|w\|^2+C\left(\left(\sum_{i=1}^{n}\xi_i\right)\right), \tag{1}$$

$$s.t\ \ y_i\left(x_i\times w+b\right)\geq 1-\xi_i,\quad \xi_i\geq 0, i=1,...,n.$$

Misclassification is asymmetric, and cost-sensitive SVM is expressed as follows.

$$R(w,\xi)=\frac{1}{2}\|w\|^2+C\left(\left(\sum_{i=1}^{n}\cos t_i\xi_i\right)\right), \tag{2}$$

$$s.t\ \ y_i\left(x_i\times w+b\right)\geq 1-\xi_i,\quad \xi_i\geq 0, i=1,...,n.$$

$\cos t_i$ is misclassification of different sample, and $\sum_{i=1}^{n}\cos t_i\xi_i$ is experience cost. C is relaxation factor, and it controls the balance of the structure and experience cost.

The optimal function for cost-sensitive SVM classification in the case of the linear separable is as follows.

$$f(x)=\mathrm{sgn}\left\{\sum_{i=1}^{n}\alpha_i^* y_i\left(x_i\cdot x\right)+b^*\right\}. \tag{3}$$

The above formula is turned into dual form by the Lagrange equation, and the optimal function for cost-sensitive SVM classification with kernel function is as follows in the case of the linear inseparable.

$$f(x)=\mathrm{sgn}\left\{\sum_{i=1}^{n}\alpha_i^* y_i K\left(x_i\cdot x\right)+b^*\right\}. \tag{4}$$

2.2 OVERSAMPLING COST-SENSITIVE SVM CLASSIFICATION

$\cos t_i$ is misclassification cost of class i, and $\cos t_{ij}\left(i,j\in 1,2,...,C\right)$ is cost of classifying i to j. $\cos t_{ii}=0\left(i,j\in 1,2,...,C\right)$. $\cos t_i=\sum_{j=1}^{C}\cos t_{ij}$.

Oversampling method can change the distribution for the training set, and copy the samples with high cost, so the distribution of each class is proportional to its cost.

The Oversampling samples number is calculated as follows.

$$\lambda=\arg\min_{i\in C}\frac{\cos t_i}{N_i},\ i=1,2,...,C, \tag{5}$$

$$N_k^*=\left\lfloor\frac{\cos t_k}{\cos t_\lambda}N_\lambda\right\rfloor.$$

N_k is the number of class k, and N_k^*-N_k is the added samples number. The added samples are replaced randomly, and the description of oversampling Cost-sensitive SVM Classification is as follows.

Input: Training sample set $S=S_1\cup S_2\cup...\cup S_C$.

Output: Oversampling Cost-sensitive SVM Classification OCS_SVM

Step 1: $S^*=S$ is new data set.

Step 2: for (i=0;i<=C;i++)

{

$$\lambda=\arg\min_{i\in C}\frac{\cos t_i}{N_i},\ i=1,2,...,C.$$

$$N_k^*=\left\lfloor\frac{\cos t_k}{\cos t_\lambda}N_\lambda\right\rfloor;$$

If ($N_k^*\succ N_k$) N_k^*-N_k samples are randomly placed into s^* from S_k;

}

Step 3: Use data set S^* to train the cost-sensitive SVM.

2.3 SUB-SAMPLING COST-SENSITIVE SVM CLASSIFICATION

Sub-sampling method changes the distribution of the train sets, and leads that the samples number is proportional to its cost. Sub-sampling method is different with oversampling, and it decreases samples with low cost.

The sub-sampling samples number is calculated as follows.

$$\lambda=\arg\max_{i\in C}\frac{\cos t_i}{N_i},\ i=1,2,...,C.$$

$$N_k^*=\left\lfloor\frac{\cos t_k}{\cos t_\lambda}N_\lambda\right\rfloor.$$

N_k is the number of class k, if $N_k^*\prec N_k$, sample numbers N_k^*-N_k in class k are decreased. The description of sub-sampling Cost-sensitive SVM Classification is as follow.

Input: Training samples set $S=S_1\cup S_2\cup...\cup S_C$.

Output: Sub-sampling Cost-sensitive SVM Classification UCS_SVM

Step 1: $S^*=S$ is new data set.

Step 2: for (i=0; i<= C ;i++)

{

S^*-S_k Samples are placed into s^*

$$\lambda=\arg\max_{i\in C}\frac{\cos t_i}{N_i},\ i=1,2,...,C.$$

$$N_k^*=\left\lfloor\frac{\cos t_k}{\cos t_\lambda}N_\lambda\right\rfloor;$$

if ($N_k^*\prec N_k$) $\left\lfloor\frac{N_k^*}{2}\right\rfloor$ samples are randomly placed into s^* from S_k ;

else S_k samples are randomly placed into s^*.

If (the samples number with class k is more than N_k^*)

Delete randomly samples.

}

Step 3: Use data set s^* to train the cost-sensitive SVM.

2.4 COST-SENSITIVE SVM CLASSIFICATION OF RECONSTITUTED SAMPLE SPACE

The sample set $X=\{(x_1,y_1),(x_2,y_2)...(x_i,y_i)...(x_n,y_n)\}$, $x_i\in R^\ell$, $y_i\in\{C_1,C_2,...C_m\}$. $p(j\mid x)$ is the probability that sample x belongs to class j, The minimum conditional risk of classifying sample x into class i is as follows by Bayes decision theory.

$$\mathrm{R}(\mathrm{i}\mid x)=\sum_j P(j\mid x)C(i,j).$$

The reconstituted training samples $\bar{y}=\arg\min_{i\in m}\{R(i\mid x)\}$.

$$\cos t_{M*\mathrm{M}}=\begin{bmatrix}\cos t(a_1,\mathrm{a}_1) & \cos t(a_1,a_2) & \cos t(a_1,a_3) & ..... & \cos t(a_1,a_M)\\ \cos t(a_2,a_1) & \cos t(a_2,a_2) & \cos t(a_2,a_3) & ..... & \cos t(a_2,a_M)\\ \cos t(a_3,a_1) & \cos t(a_3,a_2) & \cos t(a_3,a_3) & ..... & \cos t(a_3,a_M)\\ ..... & ..... & ..... & ..... & .....\\ \cos t(a_M,a_1) & \cos t(a_M,a_2) & \cos t(a_M,a_3) & ..... & \cos t(a_M,a_M)\end{bmatrix}$$

M is class number, and $\cos t(a_\mathrm{i},a_\mathrm{j})$ is cost for forecasting a_i into a_j, $\cos t(a_i,a_i)=0$.

Test sample $X=\{x_1,x_2,x_3,.....,x_n\}$, $x_i=\{x_{i1},x_{i2},x_{i3},.....,x_{id}\}$, the basic classifier f_i consumes the misclassification cost as follows.

Input: cost-sensitive SVM, training sample set $X=\{(x_1,y_1),(x_2,y_2)...(x_i,y_i)...(x_n,y_n)\}$,. $y_i\in\{C_1,C_2,...C_m\}$.

Output: Cost-sensitive SVM Classification of reconstituted sample space RS_SVM

Step1: for(i=1;i<=n; i++)

for(j=1;j<=m; j++)

Calculate $P(C_j\mid x_i)$ by Cost-sensitive SVM Classification.

Step 2: for (k=1; k<=n;k++)

{

$$\mathrm{R}(i\mid x)=\sum_{i,j\in m}P(j\mid x)C(i,j)$$

$$\bar{y}=\arg\min_{i\in m}\{R(i\mid x_k)\}$$

}

Step 3: Reconstruct training set X into $\bar{X}$.

Step 4: Reconstitute Cost-sensitive classifier RS_SVM by training set $\bar{X}$ and Cost-sensitive SVM Classification.

2.5 COST-SENSITIVE WEIGHT INTEGRATION OF CLASSIFIER

The traditional integrated learning algorithms for massive data streams prefer the classification accuracy and overall performance, and set the accuracy as weights of the base classifier. For imbalanced massive data, we must not only consider the overall performance, but also the classification accuracy of minority class, so this paper proposes the cost-sensitive weight integration. Cost matrix is as follows.

$$\mathrm{mis\_cost}_{f_i}=\sum_{i=1}^{n}\cos t(a_i,a_j). \quad (6)$$

The test for sample is also paid, and test cost of sample x_i is as follows.

$$test\_\cos t_{f_i}=\sum_{i=1}^{n}\sum_{j=1}^{d}test(x_{ij})$$

This paper integrates OCS_SVM, RS_SVM and UCS_SVM. The weight of three cost-sensitive SVM is as follows.

$$w_{f_i} = \sum_{j=1}^{n} accurcy(x_i) \Big/ \left(\text{mis\_cost}_{f_i} + test\_cost_{f_i}\right), i = 1,2,3. \quad (7)$$

Use OCS_SVM, RS_SVM and UCS_SVM in current training samples, and structure the base classifiers $\left(f_1^1, f_2^1, ..., f_k^1\right)$, $\left(f_{K+1}^2, f_{k+2}^2, ..., f_{2*k}^2\right)$, $\left(f_{2k+1}^3, f_{3k+2}^3, ..., f_{3*k}^3\right)$. Select k classifiers with higher weight for all classifiers to form $\left(f_1^t, f_2^t, ..., f_k^t\right), t \in 1,2,3$.

$$f(x) = \sum_{i=1}^{k}\left(w_{fi} * f_i^t(x)\right). \quad (8)$$

$x \in R^n$, $f_i^t(x)$ is predicted value of sample x. $f(x)$ is classification result for test sample.

3 Improved KNNModel

Guo proposed KNNModel algorithm, which extends outward by each training centre, and build the multiple models cluster for training set, so that the models cover maximum similar instances without any heterogeneous instances. KNNModel algorithm has higher classification accuracy when the samples are covered by the model clusters, but if the classified samples are boundaries, the classification accuracy is affected. The time complexity of KNNModel is high, and is not suitable for rapid classification of data stream. This paper improves KNNModeld algorithm for the concept drift detection of imbalanced massive data streams.

The training set $X = \{(x_1, y_1), (x_2, y_2), ..., (x_i, y_i), ..., (x_n, y_n)\}$, $x_i = \langle x_{i1}, x_{i2}, ..., x_{id}\rangle$, $y_i \in \{1,2,...,K\}$. Define the class cluster $unba\_class_i^k = \left(type_i^k, center_i^k, class_i^k, Tolerance_i^k, Radius_i^k, Num_i^k\right)$, $unba\_class_i^k$ is the model cluster i with class k. If class k is the minority class, $type_i^k = 1$. Otherwise $type_i = 0$. $Center_i^k = \frac{1}{Num_i^k}\sum_{y_i=i} x_i$. $class_i^k = k$ is the class of model cluster, and $Tolerance_i^k$ is tolerability. If the class is minority, $Tolerance_i^k = 0$. In other word, the model clusters of minority class are not different samples. $Radius_i^k$ is radius, and Num_i^k is sample number of model cluster.

Algorithm: Training process of BL_KNNModel

Input: Training data set X, the majority class $mc \in \{1,2,...,K_1\}$, the minority class $lc \in \{1,2,...,K_2\}$, the tolerability α for the majority class.

Output: Model cluster of each class.

Begin

For (k=1; k<=K_1;k++)

{

Use k-means algorithm to structure three cluster centre $center_1^k$, $center_2^k$, $center_3^k$ for class k.

$unba\_class_i^k = \left(type_i^k, center_i^k, class_i^k, Tolerance_i^k, Radius_i^k, Num_i^k\right), i = 1,2,3.$

}

For (k=1;k<=K_2;k++)

{

Label all samples into uncovered in class k.

Each uncovered sample is centre, and expand it the area, which covers the same class point without the other point. Each model cluster is $unba\_class_i^k = \left(type_i^k, center_i^k, class_i^k, Tolerance_i^k, Radius_i^k, Num_i^k\right), i = 1,2...$

Order degradedly the model clusters according to the samples number.

If the model cluster $unba\_class_i^k$ is covered by $\left\{unba\_class_0^k, unba\_class_1^k, ..., unba\_class_{i-1}^k\right\}$, delete it.

If the number that the model cluster covers is not more than three, delete it.

}

Structure cost-sensitive ensemble Classification.

End.

Algorithm 2: Classification process of BL_KNNMode

Input: Data streams DS, Cost-sensitive ensemble Classification, the model clusters of minority and majority class.

Output: Classification of data streams DS.

Begin

Calculate the distance form each test sample to each model centre.

If (The test sample is covered by the model clusters with the same classifier)

Label the test sample as the covered model cluster.

else if (The test sample is covered by different classifiers)

Label the classifier, which is the nearest form the test sample with the model centre.

else use cost-sensitive ensemble Classification.

BL_KNNModel runs K times k-Means cluster for structuring the model, and time complexity of k-Means cluster is $O(n_k * Num)$, and Num is cluster number, so the total complexity is $O(\max(k_1, k_2) * n_k * Num)$. $\max(k_1, k_2)$ and Num are free-running with n_k, $Num \ll n_k$, $\max(k_1, k_2) \ll n_k$, so the time complexity of BL_KNNModel is $O(n)$, and it is suitable for massive data streams classification.

4 Modules for concept drift detection

Concept drift is the characteristics of the data streams, and the overall data distribution changes over time, so that the accuracy of classification models is lower. According to concept drift problem, how to design to data streams classification model has become a hot research. At present, there are ways of instance selection, weighted instance and integration learning. This paper improves BL_KNNModel algorithm, if the density of minority class and majority class change, the concept drift occurs and the classification models should been updated. The existing concept drift detection ways use the fixed length window, but how to set the window length is difficult. The window is too long, and it is not sensitive to concept drift. On the other hand, the window is too short, and it cannot contain the enough new instances that update the model, so this paper proposes the up-and-down window. BL_KNNModel detects the massive data stream and finds the instances that are covered by any model cluster, if the uncovered instance number adds up to the fixed value $window\_length$, all current instances constitute the up-and-down windows. Detect the probability density of each model cluster, and if the differential density with previous windows exceeds the fixed threshold, the concept drift occurs.

Algorithm 3: Concept drift detection algorithm.

Input: Massive data streams DS, the probability density for each previous model cluster, the fixed $window\_length$ for the uncovered instance number, the probability density threshold τ_1 of minority class, the probability density threshold τ_2 of majority class.

Output: Occurrence of concept drift

Begin

Step 1: Run repeatedly BL_KNNModel for data streams DS, until the uncovered instance number adds up to the fixed value $window\_length$.

Step 2: Calculate the probability density of each current model cluster.

Step 3: Compare the probability density of the same model cluster in current and previous windows, if the difference exceeds the fixed threshold, the concept drift occurs.

End.

5 Cost-sensitive ensemble classifier for imbalanced data streams

The descriptions of Cost-sensitive Ensemble Classification for Imbalanced Massive Data Streams are as follows.

Input: Imbalanced Massive Data Streams $S=\{S_1,S_2,...,S_j,...\}$, the BL_KNNModel model clusters and cost-sensitive weight integration of classifier, the previous windows, the uncovered instance number $window\_length$

Output: Classification of $S_1,S_2,...,S_j,...$

Begin

i=0; l=0;

while (i<= $window\_length$)

{

Use algorithm BL_KNNModel to classify an sample S_i.

l++;

If (S_i is uncovered by any model)

i++;

}

Use algorithm 3 to test whether $\{S_1^{'},S_2^{'},...,S_l^{'}\}$ occurs concept drift.

If (Concept drift occurs)

Use BL_KNNModel to reconstruct the model that occurs concept drift, and the cost-sensitive weight integration of classifiers are also rebuilt.

Use rebuilt BL_KNNModel to classify $\{S_1^{'},S_2^{'},...,S_l^{'}\}$.

6 Simulation experiment

6.1 DATA SET

This paper selects the synthetic and real datasets. In view of rotating hyper plane, the synthetic datasets with concept drift are composed by the modified MOA Task Launcher. The sample $X=\{x_1,x_2,...,x_d,\}$. $\sum_{i=1}^{d}a_ix_i=a_0$, $a_0=r\sum_{i=1}^{d}a_i$. a_i is weight number, $r\left(r\neq 1/2\right)$ is gradient of slope of imbalanced datasets. This paper sets a series of parameters for concept drift in data streams. The parameter t is the change size of weight number a_i, The parameter $s_i\in\{-1,1\}(1\le i\le k)$ is the change direction. When a new sample is produced, a_i is adjusted by $s\bullet t$. The dimensionality for data streams is 50, the attribute varies with time, and the imbalance ratio is 0.05.

Use KDDCUP'99 as the real datasets. This paper chooses randomly Normal, Neptune and smurf as the majority, and they are negative and share 99.95%. The connection type of Land, Rootkit, Warezmaster are selected as the minority, and they are positive and share 0.5%. Sample randomly KDDCUP as the second experiment data streams which is named as Stream_KDD.

6.2 EVALUATION METRICS FOR IMBALANCED DATA STREAMS

In general, the overall accuracy is often used to measure the performance for classification model. However, the classification accuracy of the negative samples in unbalanced data streams is greater influence than the positive. Therefore, the classification accuracy is not suit for unbalanced data streams. *TP* is the positive samples number that are correctly classified and *TN* is negative. *FP* is the positive samples number that are improperly classified and *FN* is negative. This paper gives the performance evaluation as follows.

$$recall = \frac{TP}{TP + FN}, \tag{9}$$

$$Precision(\Pr) = \frac{TP}{TP + FP}, \tag{10}$$

$$G - Mean = \sqrt{\frac{TP}{TP + FN} \times \frac{TN}{TN + FP}}, \tag{11}$$

$$F - measure(Fm) = \frac{(1+\beta)^2 \times recall \times precision}{\beta^2 \times recall + precision}, \tag{12}$$

$$TPR = \frac{TP}{TP + FN}, \tag{13}$$

$$TNR = \frac{TN}{TN + FP}, \tag{14}$$

$$Mean\ Squared\ Error\ (MSE) = \frac{1}{|T|} \sum_{x_i \in T} \left(f(x_i) - p(+ \mid x_i) \right)^2. \tag{15}$$

T is test sample datasets, and $f(x_i)$ is classification result of sample x_i. $p(+ \mid x_i)$ is real posterior probability of sample x_i.

6.3 RESULT OF EXPERIMENTS

For test the efficiency of CECIDS, the test environment is Pentium D3.5GHz CPU, 8GM RAM windows 7+64bit, and select Weka+JDK6.0 as the development environment. The parameters of all algorithms refer to the papers [17, 19], and the results of synthetic datasets with concept drift are as follows. CECIDS that this paper proposes compares with RDFCSDS [16], SS [18], and OACLNIS [17], which are the other classification algorithms for imbalanced data streams.

TABLE 1 Results of synthetic datasets with concept drift

Algorithm	TPR	TNR	G-mean	Pr	Fm	MSE
SS	0.0067	0.9987	0.0923	0.9032	0.0107	0.0215
RDFCSDS	0.0246	0.9966	0.1235	0.9223	0.0345	0.0427
OACLNIS	0.0642	0.9952	0.2445	0.9465	0.1854	0.0564
CECIDS	0.0723	0.9941	0.3384	0.9668	0.2365	0.0736

The results of Stream_KDD datasets are as follows.

TABLE 2 Results of Stream_KDD datasets

Algorithm	TPR	TNR	G-mean	Pr	Fm	MSE
SS	0.0008	0.9967	0.0848	0.9254	0.0144	0.3564
RDFCSDS	0.0045	0.9943	0.1437	0.9365	0.0383	0.5324
OACLNIS	0.0093	0.9925	0.1865	0.9523	0.1624	0.6384
CECIDS	0.0102	0.9906	0.2873	0.9786	0.2413	0.8414

Form the table 1 and 2, for the evaluating indicator of TPR, G-mean, Precision, F-measure and MSE, CECIDS is higher than the other algorithms for imbalanced massive data streams, and the evaluating indicator TNR in CECIDS is lower, so CECIDS algorithm is more excellent than the other.

The classification accuracy is not suitable for imbalanced massive data streams, and this paper selects G-mean and F-measure as integrated learning curve for imbalanced massive data streams. The integrated learning curve for imbalanced massive data streams in the synthetic datasets is as follows in figure 1 and figure 2.

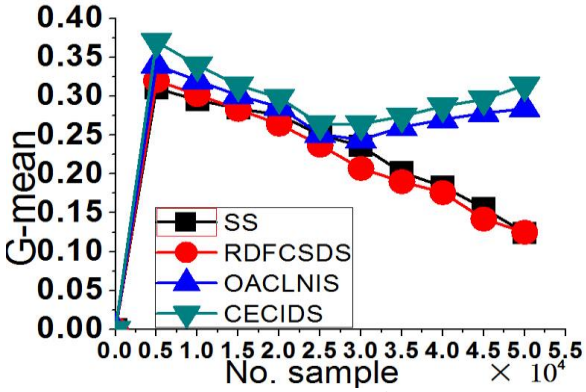

FIGURE 1 G-mean integrated learning curve for the synthetic datasets

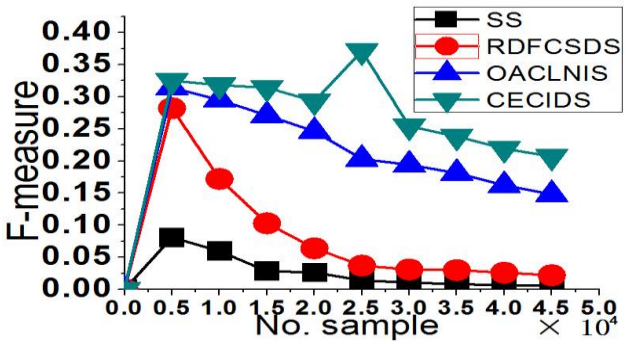

FIGURE 2 F-measure integrated learning curve for the synthetic datasets

The integrated learning curve for imbalanced massive data streams in the Stream_KDD datasets is as follows in figure 3 and figure 4.

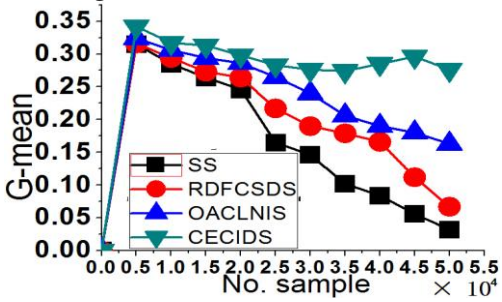

FIGURE 3 G-mean integrated learning curve for Stream_KDD datasets

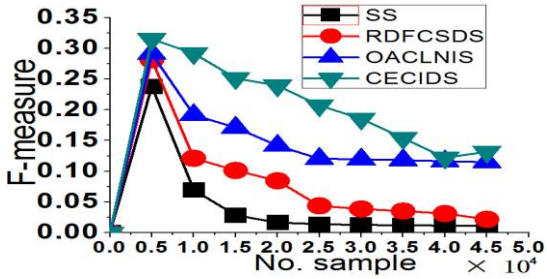

FIGURE 4 F-measure integrated learning curve for Stream_KDD datasets

From figure 1 to 4, when the data streams increase gradually, G-mean and F-measure integrated learning curve of CECIDS for synthetic and Stream_KDD datasets are more effective than the other classifiers for imbalanced data streams. Almost all the experiments validate that CECIDS that this paper proposes are more excellence than the other classification algorithms for imbalanced data streams.

7 Conclusions

The classification of concept drifting data streams has been a hot research, and this paper proposes the approach of the cost-sensitive ensemble classification for imbalanced massive data streams. A new classifier method BL_KNNModel based on KNNModel algorithm is given, which can detect the concept drift streams by using the variable windows size. By constructing the different model cluster for every class, if the concepts drift occurs on the model cluster, it only needs to rebuild the corresponding classification model. The experiments on the synthetic and real datasets prove the effectiveness of the algorithms that this paper proposes. The next work focuses on trying to adopt a new measure to calculate the distance between two samples, and distinguishes effectively the noise and concept drift.

Accurate self-localization of mobile robots based on vision sensors

Xiaoming Dong*

Department of Information and Technology Anqing Teachers college, 128 Linghu South Road, Anqing, Anhui province, China

Received 6 July 2014, www.cmnt.lv

Abstract

Robot localization is a challenging problem in indoor environment since no GPS information is available. In this paper, an algorithm was proposed for accurate localization, which designed a delicate way to extract the feature points at first, then the position of the robot was determined using the relation of the features in different images, finally, the Kalman filer was designed to decrease the error caused by robot's moving. Experiments showed the accuracy and robustness of this algorithm.

Keywords: mobile robot, multi-cues fusion, vision sensor, Kalman filer, localization

1 Introduction

Self-localization of Mobile robots is one of the most important tasks in the various applications. GPS is a commonly used technique in outer environments. However, GPS cannot be used in some special conditions such as indoor environments [1-4]. What's more, GPS cannot achieve the high accuracy required in some applications of mobile robots. Vision sensors based on cameras have long been used to implement the localization of mobile robots, which is a promising technique that improves the capability of a mobile robot to estimate its position and the speed of motion. Extensive researches have been done to make use of vision sensors in practice, monocular image sequences or stereo image sequences are used in several algorithms [5-9]; however, because of the inaccurate feature matching, there are still many difficulties to estimate the robots position effectively. The aim of this paper is to design a good method to achieve the task of localization in indoor environments.

The paper is organized as follows. In section 2, we designed a delicate way to detect the position of the distinguished feature points. Then the outlier rejection is discussed, section 3 discussed the way we used to estimate the position of robots, section 4, to decrease the error further in the time that robots move, Kalman filter is designed. In Section 4, the algorithm is verified in various experiments. Finally, the conclusions are given in section 5.

2 Feature extractions and outlier rejection

The primary idea in vision sensors is to select the distinguished features to describe the environments. How to gain the accurate point features are the most important problem in robot localization [10-12]. In our proposed algorithm, considering the real environment characters, we designed a hierarchical framework to obtain the accurate feature points. The framework mainly contains two parts, which are the global search and local search. In global search, we extract feature points as many as possible, while in local search, we only choose the feature points that have a good effect in pose estimation.

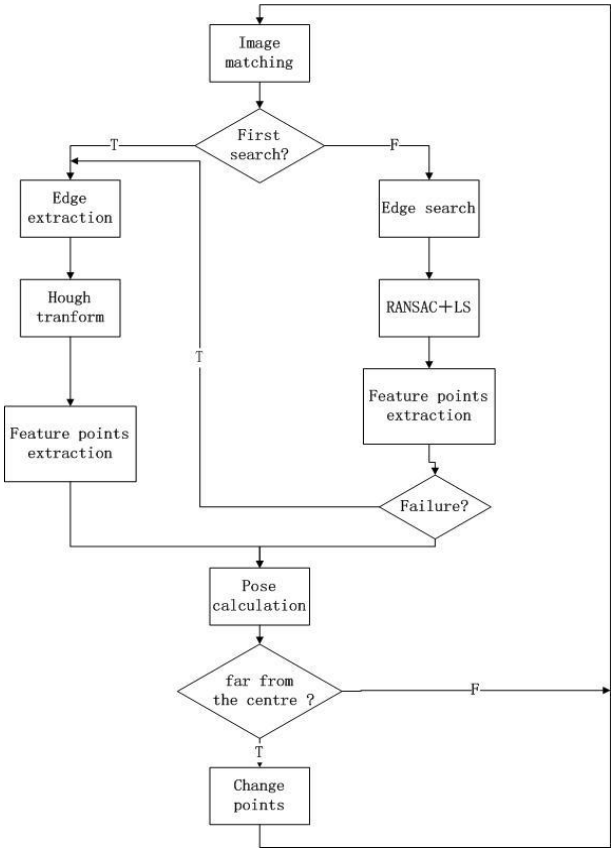

FIGURE 1 The flow graph of the feature extraction

* ***Corresponding author*** e-mail: dongxiaoming008@126.com

Figure 1 shows the detailed process, which can be described as follow:

1) When the robot is the first time to run, the edge points is to be extracted in the global scope.

2) The parameter of the lines is obtained by using Hough Transform.

3) The optimization is implemented by using least square.

4) The cross of the lines is chosen as the feature points.

Considering the speed of the calculation and the changes in the continuous images are little, so we firstly extract the lines in the neighboring area of the last image.

When the robot is not the first time to run, and the Hough transform plus the least square are implemented similarly. If it had a great change in environments, which contributes to the results that the local search loses effectiveness, the robot turns to the global search.

Integrating the two policies to extract the point features, our algorithm can get the distinguished points to pose estimation and acceptable speed. Figure 2 shows the points that robot has obtained from ceiling.

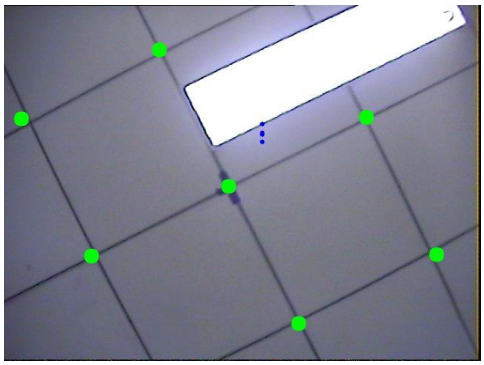

FIGURE 2 the feature points detected

For the accuracy of the point features, the method designs two steps for outlier's rejection. Firstly, an initial estimation of the homography matrix H is achieved by the RANSAC algorithm, secondly, the unmatched point features are picked out according to the homography matrix H. the process is described as follows in calculating the homography matrix based on the correspondent features: it is assumed that the correspondent features are $P_i(x_i, y_i)(i = 1,...,5)$, and then we can compute $\mathbf{H}$ as follows. P_i and V_i satisfy:

$$k\begin{bmatrix} u_i \\ v_i \\ 1 \end{bmatrix} = \mathbf{H}\begin{bmatrix} x_i \\ y_i \\ 1 \end{bmatrix}, \quad \mathbf{H} = \begin{bmatrix} m_1 & m_2 & m_3 \\ m_4 & m_5 & m_6 \\ m_7 & m_8 & m_9 \end{bmatrix}. \tag{1}$$

Eliminating k from equation (1), we can get two equations. Combining these two equations, we get:

$$\mathbf{KM} = m_9\mathbf{U}, \tag{2}$$

where $\mathbf{K}$, $\mathbf{M}$ and $\mathbf{U}$ are defined as follows $(i = 1,...,5)$:

$$\mathbf{K} = \begin{bmatrix} x_i & y_i & 1 & 0 & 0 & 0 & -x_iu_i & -y_iu_i \\ 0 & 0 & 0 & x_i & y_i & 1 & -x_iv_i & -y_iv_i \\ & & & & \cdots & & & \\ & & & & \cdots & & & \end{bmatrix}, \tag{3}$$

$$\mathbf{M} = (\mathbf{K}^T\mathbf{K})^{-1}\mathbf{K}^T\mathbf{U}. \tag{4}$$

The process can be concluded as follows:

1) Capturing the current frame and rectifying it to remove the distortion.

2) Finding out the correspondent features between the current frame and the last frame, then computing the homography matrix H to reject outliers.

3) Capturing the next frame and repeat this process.

3 Pose estimation

3.1 POSE ESTIMATION

Assuming that the coordinate of point P is $[x_w, y_w, z_w, 1]^T$ in the world coordinate system, then the Equation (5) is satisfied, the Equation (5) is called external parameter model of camera.

$$\begin{bmatrix} x_c \\ y_c \\ z_c \\ 1 \end{bmatrix} = \begin{bmatrix} {}^cn_{wx} & {}^co_{wx} & {}^ca_{wx} & {}^cp_{wx} \\ {}^cn_{wy} & {}^co_{wy} & {}^ca_{wy} & {}^cp_{wy} \\ {}^cn_{wz} & {}^co_{wz} & {}^ca_{wz} & {}^cp_{wz} \\ 0 & 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} x_w \\ y_w \\ z_w \\ 1 \end{bmatrix} = \begin{bmatrix} R & p \\ 0^T & 1 \end{bmatrix}\begin{bmatrix} x_w \\ y_w \\ z_w \\ 1 \end{bmatrix} = {}^cT_w\begin{bmatrix} x_w \\ y_w \\ z_w \\ 1 \end{bmatrix}. \tag{5}$$

As the Figure 3 shows, on the time i when the robot is moving, the reference coordinate system Or_i is set up in the cross point between the ceiling and the optic axes, And the axis direction of the reference coordinate system is the same as the world coordinate system, Similarly, the reference coordinate system Or_{i+1} is set up too.

When the camera moves from point Oc_i to Oc_{i+1}, the process can be decomposed into two parts: the one is the rotation of the robot around axis Zc_i and the other one is the translation from point Oc_i to point Oc_{i+1}. Then the relative position will be calculated if the position of the feature point P_j in the reference coordinate system is obtained between time i and time i+1.

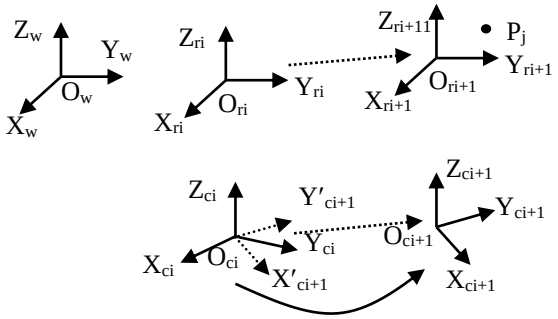

FIGURE 3 The coordinate system in different time

The transform of the reference coordinate can be described as equation 6 in the time *i*.

$$ {}^{i}T_{ri} = \begin{bmatrix} {}^{i}n_{wx} & {}^{i}o_{wx} & {}^{i}a_{wx} & 0 \\ {}^{i}n_{wy} & {}^{i}o_{wy} & {}^{i}a_{wy} & 0 \\ {}^{i}n_{wz} & {}^{i}o_{wz} & {}^{i}a_{wz} & {}^{c}p_{rz} \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{6} $$

The distance between the camera axis and the feature points is required in the localization. If the camera plane is parallel to the ceiling, it would be a constant. Considering the camera axis O_c is the same both in the reference coordinate system and in the world coordinate system, this can be calculated based on the Equations (5) and (6).

$$ \begin{cases} ({}^{i}n_{wx} - {}^{i}x_{1cj}\,{}^{i}n_{wz})\,{}^{i}x_{rj} + ({}^{i}o_{wx} - {}^{i}x_{1cj}\,{}^{i}o_{wz})\,{}^{i}y_{rj} = {}^{i}x_{1cj}\,{}^{c}p_{rz} \\ ({}^{i}n_{wy} - {}^{i}y_{1cj}\,{}^{i}n_{wz})\,{}^{i}x_{rj} + ({}^{i}o_{wy} - {}^{i}y_{1cj}\,{}^{i}o_{wz})\,{}^{i}y_{rj} = {}^{i}y_{1cj}\,{}^{c}p_{rz} \end{cases}. \tag{7} $$

In the above equations, ($^{i}x_{rj}$, $^{i}y_{rj}$) represents the P_j coordinate and ($^{i}x_{1cj}$, $^{i}y_{1cj}$) represents the normalized coordinate of the image focus.

Then, the coordinate of feature P_j can be calculated in the reference coordinate system of different time.

Because in time *i* and time *i*+1, the transform matrix between the references coordinate system and the camera ordinate system can be represented as Equation (8):

$$ {}^{ri}T_{i} = \begin{bmatrix} {}^{i}n_{wx} & {}^{i}n_{wy} & {}^{i}n_{wz} & -{}^{i}n_{wz}\,{}^{c}p_{rz} \\ {}^{i}o_{wx} & {}^{i}o_{wy} & {}^{i}o_{wz} & -{}^{i}o_{wz}\,{}^{c}p_{rz} \\ {}^{i}a_{wx} & {}^{i}a_{wy} & {}^{i}a_{wz} & -{}^{i}a_{wz}\,{}^{c}p_{rz} \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{8} $$

The localization of the robots can be calculated by iteration based on the equation (9):

$$ \begin{cases} p_{xi+1} = p_{xi} + {}^{i}x_{rj} - {}^{i+1}x_{rj} - {}^{i+1}n_{wz}\,{}^{c}p_{rz} + {}^{i}n_{wz}\,{}^{c}p_{rz} \\ p_{yi+1} = p_{yi} + {}^{i}y_{rj} - {}^{i+1}y_{rj} - {}^{i+1}o_{wz}\,{}^{c}p_{rz} + {}^{i}o_{wz}\,{}^{c}p_{rz} \end{cases}. \tag{9} $$

3.2 ERROR ANALYSIS AND FILTERING

To analyze the error, we set up the moving model of the mobile robot at first, and then the Kalman filter is designed to decrease the error. The robot used in this paper is a wheel robot, its model is shown in Figure 4, assuming that SL represents the distance of the left wheel moves and SR is that of right wheel. The rotation angle of the wheel axis is $\Delta\theta$, θ is the intersection angle, then the relation between the current pose and the last pose can be referred, assuming that $X_i(x_i, y_i, \theta_i)$ is the current pose and $X_{i-1}(x_{i-1}, y_{i-1}, \theta_{i-1})$ is the last pose.

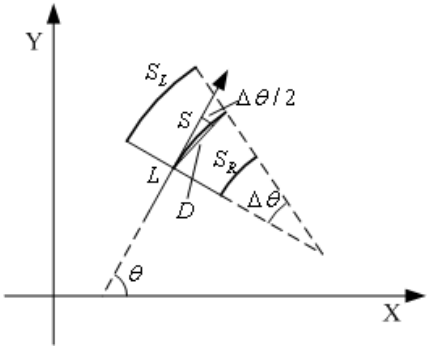

FIGURE 4 The moving model of robot wheels

Then the relation between the rotation angle and the distance the robot moves is:

$$ \Delta\theta = (S_L - S_R)/L\,. \tag{10} $$

The arc length, which is the distance the robot centre has moved, can be represented as follows:

$$ S = (S_L + S_R)/2\,. \tag{11} $$

And *D* can be referred as:

$$ D/2 = S/\Delta\theta \times \sin(\Delta\theta/2)\,. \tag{12} $$

Considering that S_L and S_R are very close, it can be assumed that:

$$ \Delta\theta = 0\,, \tag{13} $$

$$ \begin{aligned} \Delta x &= S \times \cos\theta, \\ \Delta y &= S \times \sin\theta. \end{aligned} \tag{14} $$

Updating the current pose:

$$ X_i = X_{i-1} + (\Delta x, \Delta y, \Delta\theta)\,. \tag{15} $$

Considering the noise, the formula of the pose can be changed as:

$$ X_i = F(X_{i-1},\, S_{Li-1},\, S_{Ri-1}) + W_i\,, \tag{16} $$

where W_{i-1} is assumed as gauss noise and its average value and the variance are:

$$ \mathrm{E}[W_i] = 0,\ \mathrm{E}[W_i, W_i^{\mathrm{T}}] = Q_i\,. \tag{17} $$

Covariance can be modeled as diagonal matrix, the diagonal entries are:

$$Q_{11} = K_x |S\cos\theta|,$$
$$Q_{22} = K_y |S\sin\theta|, \quad (18)$$
$$Q_{33} = K_{S\theta}|S| + K_{\theta\theta}|\Delta\theta|,$$

where K_x and K_y are drift coefficients the robot moves along the axis X and axis Y, similarly, $K_{S\theta}$ and $K_{\theta\theta}$ is the drift coefficients of angles. The values of the coefficients can represent the error. The more the coefficients, the more the errors.

For the more accurate localization, we choose the extended Kalman filter, in EKF framework; the moving model can be represented as:

$$x_t = f(x_{t-1}, u_{t-1}, w_{t-1}). \quad (19)$$

And the observation model is:

$$z_t = h(x_t, v_t). \quad (20)$$

Then, state prediction and observation prediction can be determined as:

$$\hat{x}_t^- = f(\hat{x}_{t-1}, u_{t-1}, 0), \quad (21)$$

$$\hat{z}_t^- = h(\hat{x}_t^-, 0). \quad (22)$$

Using tailor Equation to linear the models, the updating equation in EKF is:

$$\hat{x}_t^- = f(\hat{x}_{t-1}, u_{t-1}, 0),$$
$$P_t^- = A_t P_{t-1} A_t^T + W_t Q_{t-1} W_t^T. \quad (23)$$

And the observation model updating equation is:

$$K_t = P_t^- H_t^T (H_t P_t^- H_t^T + V_t R_t V_t^T)^{-1},$$
$$\hat{x}_t = \hat{x}_t^- + K_t(z_t - h(\hat{x}_t^-, 0)), \quad . \quad (24)$$
$$P_t = (I - K_t H_t) P_t^-.$$

In the design, we set up the observation model according to the character of the vision sensors and decrease the error further.

4 Experiments and analysis

Various experiments have been carried out using the mobile robot. The camera is precisely calibrated beforehand and is mounted on the center of the robot fixedly.

The inner calibration parameter is shown in Table 1 and Table 2. They represent the focus and the center respectively of left camera and right camera.

TABLE 1 The inner parameter of calibration (mm)

Inner parameter	**kx**		**ky**	
	result	*variants*	*result*	*variants*
Left camera	568.27	2.44	566.21	2.76
Right camera	569.35	3.18	569.58	2.98

TABLE 2 The center of the camera (mm)

u0		**v0**	
result	variants	result	variants
228.77	2.19	183.25	2.35
232.12	2.91	177.98	1.98

The external parameter is shown in Tables 3 and 4, which are the parameter of the rotation and the translation respectively. And the unit is mm. the values represent the relative angle and translation between the two cameras.

TABLE 3 Translation vector of the external parameter (relative to the left camera)

Translation vector P(mm)	result	445.83	6.54	8.25
	variants	4.23	3.15	2.86

TABLE 4 Rotation vector of the external parameter (relative to the left camera)

	variance	0.05342 0.03425 0.00978

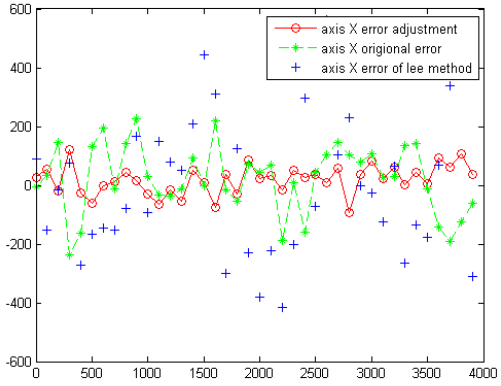

FIGURE 5 The error comparison of axis X

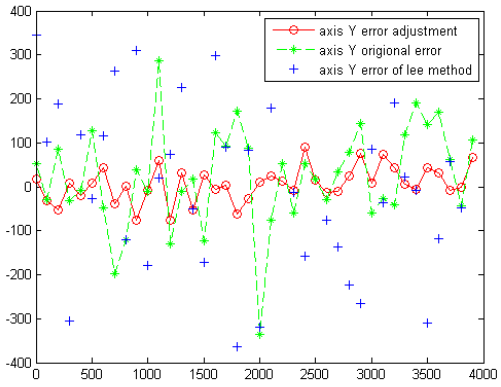

FIGURE 6 The error comparison of axis Y

The comparison is implemented between the method we proposed and the famous Lee method [13], because the accurate feature extraction, the error of our method is about 100mm or so, while the Lee algorithm is about 200mm, the error is decreased further through the Kalman

filter, which is about 50mm after filter. Figure 5 gives the error of axis *X* and Figure 6 gives that of axis Y. The figure shows that the effect of robot localization has been greatly improved.

5 Conclusions and future work

In the various applications, Vision sensor is one of the most important sensors because it can provide larger amount of information comparing with other traditional sensors. In this paper, an effective method is proposed for accurate robot localization. The experiments show its accurateness. Vision sensor has its shortcoming that the features in image would be affected when the environment has great changes. Future work will consider more about the robustness of the Vision sensors, the combination of the traditional sensor and the Vision sensors maybe a possible way to resolve this problem.

Abstract

The removal of the unfertilized egg from the hatching egg before the incubation could improve the efficiency of incubation. The identification of the unfertilized and fertilized eggs by hyperspectral imaging technology combined with GA-BP algorithm was proposed. The comparative analysis for the unfertilized and fertilized eggs was implemented by different pretreatment and principal component. In order to improve the performance of BP neural network, GA algorithm was used to optimize the network parameters. The application of GA-BP network was established the qualitative detection model. The results of the study showed that the MSC + SD pretreatment method was the most suitable for the model. The determination coefficient was 0.95, which indicated the optimized network model had a good generalization ability and high prediction precision with unfertilized eggs accuracy being 93%, fertilized eggs accuracy being 94%, the overall accuracy being 93.5%. The results indicated that the method of non-destructive identification for fertilized and unfertilized eggs based on hyperspectral imaging technology combined with GA-BP algorithm was feasible.

Keywords: hyperspectral imaging technology, before incubation, hatching eggs, identification, GA-BP

1 Introduction

Identification of unfertilized eggs before the incubation is one of the difficult problems in the hatchery industry, which has no reasonable solution yet. Hatchery statistics show that about 8%-9% of all incubated eggs do not hatch due to unfertilized eggs [1], which lead to huge waste of time, space, labour force and energy. In practical applications, candling eggs after 7 to 12 days of incubation are always used, but the pick-out unfertilized eggs have lost edible value, which lead to economic loss. The non-destructive identification of unfertilized eggs before incubation as early as possible can optimize space, save labour and energy, avoid contaminating of other eggs and bring better profits to hatcheries.

In recent years, many scholars have worked with the hatching eggs non-destructive detection using machine vision [2], acoustic pulse vibration [3], optical method [4], nuclear magnetic resonance imaging [5], hyperspectral and so on [6, 7], who have also made certain research progress, but mainly concentrated in the middle of hatching egg quality detection. Our group have used near infrared diffuse reflection for hatching egg quality detection [8], which made some achievements, but need to improve precision. High spectral technology as a new detection technology has a super multichannel, high spectral resolution, narrow band, wide spectral range. It is the perfect combination of image and spectrum technology, which can obtain both image information and spectral information. So more and more people get the attention of hyperspectral image technology in non-destructive testing of the quality of agricultural products, especially widely used in detecting the quality and safety of livestock products, fruits and vegetables [9, 10]. In recent years, some scholars used hyperspectral image technology for detection of unfertilized and fertilized eggs, but they are mainly research on the detection during the early period. The main purpose of this study was to explore the feasibility of hyperspectral image technology on the unfertilized and fertilized eggs detection before the incubation.

2 Materials and method

2.1 EGG SAMPLES

Two hundred eggs including 100 fertilized eggs and 100 unfertilized eggs were collected from Huazhong Agricultural University Hatchery within one week, which were obtained from 50-55-wk-old Single Comb White Leghorn chickens. We randomly chose, for each class, 60% of the subset to build the training set (60 fertile eggs and 60 infertile eggs) and the remaining 40% was put aside for testing set (40 fertile eggs and 40infertile eggs). Corresponding training set and testing set were 120 and 80 samples respectively. After cleaned, all the samples were numbered.

[*]***Corresponding author*** e-mail: zzh@mail.hzau.edu.cn

2.2 TESTING SYSTEM

The Headwall Hyper spectral imaging spectrometer (HS-VNIR N-series) was used, which had 400 nm to 1000 nm spectral range. The hyperspectral image acquisition system was shown in Figure 1. In order to ensure that the sample uniform illumination, six halogen tungsten lamp (Philips, 35W) were displaying asymmetric distribution to form DC circular lighting system. The main working parameters were set as following: the exposure time was 5 ms; the interval of the conveyer was 120 μm; spectrum sampling interval was 0.8 nm; scanning length was 70 mm.

ENVI V. 4.3 (Research System, Inc., USA) and MATLAB V. 7.0 (MathworksCo., USA) software were used to process the data of hyperspectral image. Hyperspectral images were 3D data blocks, each pixel in the image corresponded to one spectrum. 10556 pixels of the elliptical area of egg image were selected to be region of interest (ROI) (the green part in the Figure 2a). The average of the spectrum, which was obtained by the calculation of all pixels in the ROI, was regards as the reflection spectrum of eggs (the white part in the Figure 2b).

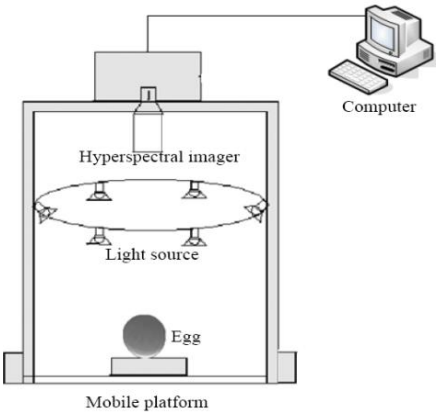

FIGURE 1 Hyperspectral imaging system

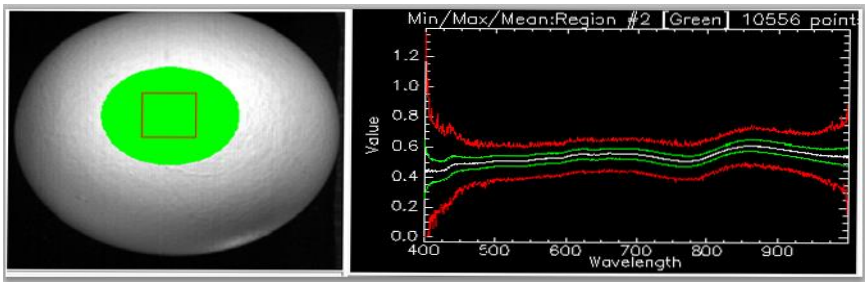

FIGURE 2a Marking of ROI

FIGURE 2b Spectral information of ROI

2.3 THE CALIBRATION OF IMAGES

The uneven light intensity distribution and dark current noise, which existed in the working process of hyperspectral image acquisition system, would cause that the image with the weak light intensity distribution of band contained larger noise. Therefore black and white calibration should be implemented for the hyperspectral image [11]. Before collecting all sample images, the black calibration image *B* was collected with covering lens, and white calibration image *W* was collected by scanning calibration standard white plate, then according to the formula (1), absolute image *I* was converted relative image *R*.

$$R = \frac{I - B}{W - B}. \quad (1)$$

2.4 EGGS ASSESSMENT

The eggs were sent to incubator for hatching after scanned by hyperspectral image acquisition system. The incubator was sterilized by formaldehyde solution fumigation and worked for 24 hours in predefined temperature and humidity conditions before the eggs were put in. The incubator temperature was 38.5 ℃ and the relative humidity was 65%. It was difficult to distinguish unfertilized eggs from fresh hatching eggs by their morphology. Only after hatched for four days, they could be distinguished by candling. The fertilized eggs would appear blood spots through candling in the fourth day, at the same time, unfertilized eggs had no embryonic development phenomenon. According to candling at the fourth day, the actual type of unfertilized eggs and fertilized eggs were determined. If it could not be distinguished clearly, the egg would be broken and observed whether the embryo has developed or not.

2.5 GA-BP NETWORK ALGORITHM

Back-Propagation (BP) neural network has strong nonlinear mapping ability and flexible network structure. But it is easy to fall into local minimum, slow convergence speed and so on. Genetic algorithm (GA) is a kind of adaptive global optimization probability search algorithm based on natural selection in the formation of biological and genetic processes. GA was used to optimize the initial weights and threshold of BP neural network. The optimal initial weights and thresholds were obtained through selection, crossover and mutation operation of GA, which could overcome the random defects of connection weights and thresholds of BP neural network [12]. GA-BP neural network not only played the mapping ability of BP neural network generalization, but also made BP neural network has fast convergence and strong learning ability. The specific algorithm flowchart was shown in Figure 3.

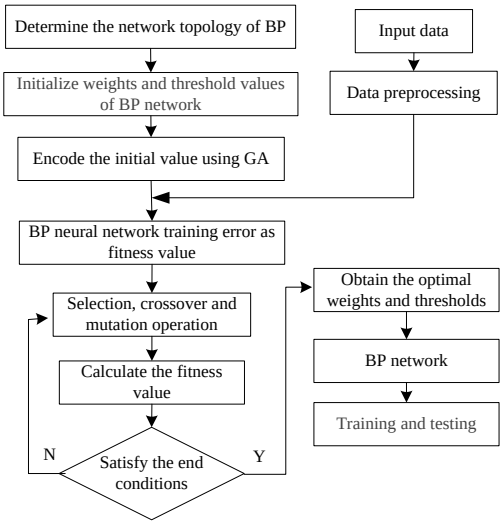

FIGURE 3 The flow chart of GA-BP neural networks

3 Results and discussion

3.1 PREPROCESSING AND DIMENSIONALITY REDUCTION

The spectrum extracted from eggs contained not only the information of the eggs themselves, but also information and noises from eggshell, background and instruments. Therefore, some pretreatments must be taken for the egg spectra to remove the useless information. In this paper, 10 kinds of pretreatment methods were used for the spectra data, which included the first order derivative(FD), the second order derivative (SD), multiplicate scatter correction (MSC), the standard normalization(SNV) and the combination of MSC+FD, MSC+SD, SNV+FD, SNV+SD, FD+SM, SD+SM. The following only gave the original spectra (Figure 4) and pre-treated spectra with MSC+SD (Figure 5). From Figure 4, two kinds of egg original spectra had the same general trend and small differences, while after pretreatment (Figure 5), the features of image peaks and valleys, lifting trend were more obvious. At the same time, the differences of fertilized and unfertilized eggs in some range of peaks and valleys were widened so that it was easier to distinguish them. Further it could be seen that the original spectral values range in each band was larger, but the spectral values of the samples after the pre-processing were concentrated in a small interval, which made the feature more obvious and was beneficial to classification. After analysis and comparison, it could be seen that the differences of spectra between the fertilized and unfertilized eggs were mainly concentrated within the wavelength range of 400 nm~500 nm, 700 nm~900 nm.

In order to reduce the dimension of hyperspectral data, principal component analysis (PCA) was used to analysis above ten kinds of pretreatment of spectrum respectively. When the cumulative contribution rate of the eigenvalues of the covariance matrix exceeded 90%, the corresponding principal components were selected. The statistical results were shown in Table 1. From Table 1, it could be seen that the number of the variables were greatly reduced by using PCA so that it could improve of training speed and precision of the neural network model.

3.2 CLASSIFICATION OF BP NETWORK

BP neural network was worked as a classifier in this experiment. The 200 samples were randomly divided into a training set and a test set. First, the data that was pretreated in different ways should do principal component analysis. The principal component variables instead of the original variables were used as the input of the neural network, and then built the BP neural network for training. The training times was 2000; error performance objectives was 10^{-4}, and the learning rate was 0.01. The average of accuracy and coefficient of determination was used to evaluate the neural network in the number of this hidden layer. The programs had run 10 times and the results were shown in Table 2. As could be seen from Table 2, the model worked best after MSC + SD data preprocessing. So MSC + SD could be determined as the best pretreatment way. Corresponding network structure were one hidden layer and three hidden layer nodes. But average accuracy rate of the network prediction was only 83% and decision coefficient is only 0.57 after the optimal pretreatment. Also, classification accuracy of the network was not satisfactory. In the absence of initial weights threshold value, BP network were randomly assigned to each training weights threshold, causing instability in the models and turbulence in the training results. Therefore, it was necessary to further optimize the parameters of the network in order to improve the network performance.

3.3 GA-BP NETWORK OPTIMIZATION

The neural network structure that previously constructed was established by the 7-3-1. The total number of weights was 24(7 * 3 + 3 * 1 = 24) and the total number of threshold was 4(3 + 1 = 4), so the encoding length of individual of genetic algorithm was 28 (24 + 4 = 28). We randomly chose from original training set of 120 samples, for each class, 80 eggs of original training set to build the training subset (40 fertile eggs and 40 infertile eggs) and the remaining all was put aside for testing subset (20 fertile eggs and 20 infertile eggs). The absolute value of the training data prediction error was regard as the individual fitness value, the smaller the fitness value, the more preferably individuals.

The genetic algorithm parameters were set as follows: population size was 10, evolution was 100 times; crossover probability was 0.4; the variation coefficient was 0.2. In the process of the genetic algorithm to

optimize, the best individual fitness value changed as shown in Figure 6.

The optimal weight and threshold value of BP neural network were obtained by the genetic algorithm, which were shown in Table 3.

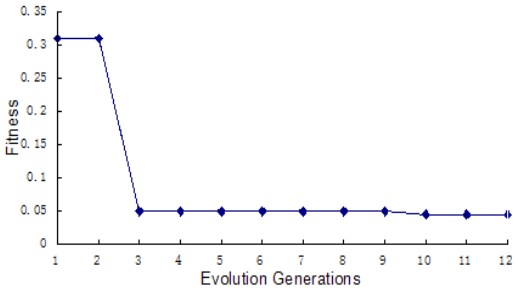

FIGURE 6 The best single adaptive by GA

3.4 TESTING OF OPTIMIZED BP NETWORK

The optimized BP network was used to test the 80 samples of original test set. Ten replicates were performed. Table 4 showed that using the BP network model predicted 10 times of classification accuracy and determination coefficient. It could be seen that unfertilized egg accuracy was 93%; fertilized eggs accuracy was 94%; among the 10 replicates testing, the extreme maximum accuracy of fertilized and unfertilized egg was 100% and 97.5% respectively; the extreme minimum accuracy of fertilized and unfertilized egg was 90% and 87.5% respectively; the overall accuracy of 93.5%, and the determination coefficient was 0.95. The result showed the network had high prediction precision and good generalization ability.

TABLE 4 The prediction results by 10 times tests

Egg type	Extreme maximum accuracy	Extreme minimum accuracy	Average accuracy	Total accuracy	Determination Coefficient
Fertilized egg	100%	90%	94%	93.5%	0.95
Unfertilized egg	97.5%	87.5%	93%		

4 Conclusions

In this research, an attempt has been made to preprocess spectral data, reduce data dimension and classify the unfertilized eggs using GA-BP network. Classification accuracy was 93.5%, which was encouraging. The results showed that MSC+SD pretreatment method was the most suitable for the model, PCA reducing data dimension was effective and hyperspectral technology combined with GA-BP network to identify unfertilized eggs and fertilized eggs was feasible.

Abstract

Association rules tell us interesting relationships between different items in transaction database. Traditional association rule has two disadvantages. Firstly, it assumes every two items have same significance in database, which is unreasonable in many real applications and usually leads to incorrect results. Secondly, traditional association rule representation contains too much redundancy which makes it difficult to be mined and used. This paper addresses the problem of mining weighted concise association rules based on closed itemsets under weighted support-significant framework, in which each item with different significance is assigned different weight. Through exploiting specific technique, the proposed algorithm can mine all weighted concise association rules while duplicate weighted itemset search space is pruned. As illustrated in experiments, the proposed method leads to better results and achieves better performance.

Keywords: weighted concise association rule, transaction database, closed itemset, support-significance

1 Introduction

Extensive studies have been devoted into association rules mining in data mining area [1-4]. Association rule is an important knowledge representation and it tells us significant relations among itemsets present in large number of transactions [5-8]. Association rules generation has two steps [9-12]: one is to mine all the itemsets, and the other is to enumerate association rules. Reference [13] focused on the need for generating hierarchical minimal rules that provide maximal information and an algorithm has been proposed to derive minimal multilevel association rules and cross-level association rules that has made significant contributions in mining the minimal cross-level association rules, which express the mixed relationship between the generalized and specialized view of the transaction itemsets. In Reference [14], in order to solve the difficult concept association mining of query keywords in the semantic search, it raises a method of extracting concept association based on hierarchical clustering and association rules. Firstly, quick updating algorithm of association rules is adopted to extract non-categorization relationships of key words in the paper. Meanwhile, improved method of hierarchical clustering is used for the extraction of categorization relation while how to find father node for leaf nodes of the hierarchical clustering tree is provided as well. Reference [19] proposes a new algorithm for fast frequent itemset mining, which scan the transaction database only once which all the frequent itemsets can be efficiently extracted in a single database pass. To attempt this objective, it define a new compact data structure, called ST-Tree (Signature Transaction Tree), and a new mining algorithm ST-Mine to extract frequent itemsets.

But above association rule mining methods has two disadvantages as follow [13-16]. First, it assumes every two items have same significance in transaction database. Obviously it is unreasonable in real applications, which usually leads to incorrect results biased with users' expectation in real applications. Second, traditional representation contains too much redundancy which often makes the mining process and results are flooded in the combinatorial explosion of insignificant relationships.

In fact, one item may be different greatly from the other for the semantics in different real context. It is impossible to express all the differences absolutely between them. Attaching different weights to items with different significances is a good alternative in many circumstances. In real circumstance, general association rule must be re-defined to derive the result selectively referring to the weights on items and make more reasonable results [17-20].

In this paper, association rule under weighted framework and its mining methods are respected. Weighted concise association rule is re-defined through exploiting weighted support-significant framework. We find that it is possible to define weighted concise association rule based on closed itemset when the "downward closure property" holds. We can mine the whole set of weighted closed itemsets. The first step of association rule generation can be completed. Through exploiting the depth-first mining strategy and exactly itemset checking approach, duplicate closed itemsets can be identified early. In the second step, weighted concise association rules are enumerated. Weighted concise

itemsets are arranged according to the item sequences based on tree structure. We gear the rule generating sequence to concise itemsets generating sequence, so that they can be processed concurrently. Additionally much space can be saved. Experimental studies are conducted to show that the method in this paper is reasonable and achieves good results.

2 Basic theory

Let $I=\{i_1, i_2, \ldots, i_m\}$ be a set of items and $TDB=\{T_1, T_2, \ldots, T_n\}$ be a transaction database, where $T_i(1\leq i\leq n)$ is a transaction which contains a set of items in I. A set of items is called an itemset or a pattern. A transaction T is said to contain itemset X if and only if $X\subseteq T$. The number of transactions in TDB that contain X is called the support count of X, denoted as count(X), and the support of X is denoted as support(X), which equals to count(X)/|TDB|, where |TDB| is the total number of transactions in TDB [21-24].

Given the form $X\Rightarrow Y$, the confidence of X is denoted as confidence($X\Rightarrow Y$), which equals to support ($X\cup Y$)/support(X) [21].

Definition 1. Weighted item. Given a transaction database TDB, and the item sets $I=\{i_1, i_2, \ldots, i_n\}$ which appear in TDB. We attach a value w_m to each i_m representing its significance. Such an item is called **weighted item**. And its weight is denoted weight(i_m) or weight($\{i_m\}$), which equals to w_m.

The items' weights may be defined respectively in different areas to balance the significance between items in transaction database [22].

Definition 2. Weighted itemset. Given a itemset X, for each item in it has a weight, itemset X may take different significance beyond the other. We denote the significance of X weight(X), which varies according to the itemset X.

Given an itemset X, from above definition, we define the weighted support of X as ws(X) [23].

Definition 3. Weighted closed itemset. Given a transaction database TDB and a minimum support threshold ξ_1, an itemset X is a frequent weighted closed itemset if both of the following conditions are true [24]:

1) $ws(X)\geq\xi_1$;

2) $\forall Y\supset X$ such that $ws(Y)<ws(X)$.

The problem of weighted closed itemsets mining is to find the complete set of frequent weighted closed itemsets in a given transaction database with respect to the given support threshold ξ.

Definition 4. Weighted concise associateion rule based on closed itemset. Given a transaction database TDB and a minimum support threshold ξ_1 and a minimum confidence threshold ξ_2, and rule $X\Rightarrow Y$ is a weighted concise association rule based on closed itemset if both of the following conditions are true [20]:

1) X, Y($Y\supset X$) are frequent weighted closed itemsets;

2) $ws(Y)/ws(X)\geq\xi_2$.

The problem of **weighted concise association rule mining** is to find the complete set of weighted concise association rule based on closed itemsets in a given transaction database with respect to the given support threshold ξ_1 and confidence threshold ξ_2.

In order to improve the efficiency of rule mining algorithm, we often employ the following two basic properties [9]:

1). Any loophole of frequent itemsets collection is also frequent itemsets.

2). Any superset of the frequent itemsets is also frequent itemsets.

The above two properties are basic pruning strategy of Apriori algorithm, called them Apriori properties.

From the above two properties of the Apriori known, if an itemset contains the infrequent k - itemsets, so the itemset must be infrequent itemsets. The process of mining in the subsequent can delete them. From this perspective, by means of connecting all frequent k-itemsets in the process of mining, we can obtain all candidate (k + 1) - frequent itemsets. This can reduce the size of the candidate itemsets. Apriori algorithm scans affairs library for the first time, calculates the support degree of each item to obtain the set of frequent 1 - itemsets which compliance with minimum support threshold. In after the first k times scanning library, it firstly obtained a new potential a set of candidate frequent k – itemsets based on the collection of frequent k-1-itemsets. Then calculates the support degree of each item, finally selected from a candidate set of frequent k – itemsets, which is in line with the minimum support threshold, and will serve as a collection of transactions on the basis of the next scan, and cycle to repeat the process until the termination conditions to achieve algorithm.

In above process, the procedure delete (L_{k-1}), the procedure candidate_gen (L'_{k-1}), the procedure has_infrequent_subset (c, L'_{k-1}) and the procedure join (l_1,l_2) were adopted [11, 12]:

Procedure Delete (L_{k-1})

//delete the item-sets whose item number is less than k-1 from L_{k-1} ;
Begin
Given $\forall$item Initial value i.count=0
{
For all l in L_{k-1} item-set part
If $i\in l$
Then i.count++// calculates the emerging times of item i in l;
}
If (i.count<k-1) then
{
For all l in L_{k-1} item-set part
If $i\in l$
Then delete the frequent item-sets of l from L_{k-1} ;
}
Return L_{k-1} .
End

Procedure Candidate_gen(L'_{k-1})

//generate k-item candidate set
Begin
For ∀item-set $l_1 \in L'_{k-1}$
For ∀item-set $l_2 \in L'_{k-1}$
If the first k-2 items of l_1 *and* l_2*are the same while those of the first k-1 item-sets are different*
Then c=jion(l_1*,*l_2*)// connect them to generate candidate item-set set;*
If has_infrequent_subset(c, L_{k-1} *)*
Then delete c;// prune to delete the non-frequent candidate item-sets
Else put c into C_K *;*
return C_K *;*
End

Procedure jion(l_1,l_2)

Begin
Command that:
The item-set part of l_1 *and* l_2 *are respectively are* l'_1、l'_2 *;*
The indicating transition sets are l_1^1、l_2^2 *;*
$l_c = l_1' \infty l_2'$ *is the item-set part after connecting c,* $l_c^c = l_1^1 \cap l_2^2$ *is the transition set part of c;*
Return c;
End

Procedure has_infrequent_subset(c, L'_{k-1} **)**

//judge whether the subsets of L'_{k-1} *are non-frequent sets;*
Begin
for each (k-1)-subset s of c item-set part
if s $\notin L'_{k-1}$ *item-set part*
Then return true;
Return false;
End.

3 Weighted concise association rules based on closed itemsets

In this section, we explore properties of weighted concise association rules based on closed itemsets. First, weighted closed itemsets should be enumerated. In definition 3, frequent weighted closed itemset is defined. But it is difficult to decide how to calculate the weights of itemsets reasonably to mine the complete set of weighted closed itemset and rules properly. Different definitions of itemset's weight may lead to different results, but properties of traditional closed itemset may not hold. The total itemset search space will be viewed, which is impossible. And we must ensure that all weighted association rules generated can be derived from concise ones, and duplicate itemsets and search space can be pruned efficiently while mining weighted concise association rules [21].

Traditional itemsets will come less frequently when being added to items while being enumerated. Then the enumerating process can be stopped when infrequent itemsets are found. If the "Anti-monotone" property of itemset does not hold on weighted itemset, we may not know when the enumerating process will be stopped. Otherwise, weighted concise association rules can be generated in depth–first like manner properly. A weighted support-significant framework is adopted to keep "downward closure property". In the mining process, the method of calculating weighted support of an itemset is adopted. We prove that weighted closed itemset keeps the anti-monotone properties. All weighted concise association rules can be mined and all weighted association rules can be derived from concise ones.

Definition 5. Weighted support of itemset. Given a transaction database TDB and each transaction T_i in it is attached a weight tw_i. Then the weighted support of itemset X is defined as follow:

$$ws(X) = \frac{\sum_{T_i \in TDB \cap X \subseteq T_i} tw_i}{\sum_{T_i \in TDB_i} tw_i}. \quad (1)$$

For any $T_i \in$TDB, we can define ws(T_i) reasonably. Generally weighted support of itemset X is defined as follow:

$$ws(T_i) = \frac{\sum_{I_j \in T_i} weight(I_j)}{|T_i|}. \quad (2)$$

Lemma 1. (downward closure property). For an itemset X, $\exists Y \supset X$, ws(Y)≤ws(X).

Lemma 2. For an itemset X, $\exists Y \supset X$, ws(Y)=ws(X), then X can't be a weighted closed itemset.

Proof: From definition 4, we can have the lemma 2.

Lemma 3. For two itemsets X, Y($Y \supset X$), ws(Y)=ws(X), then ∀ Z ($Y \supset Z \supset X$), Z isn't a weighted closed itemset.

Proof: Let TS(X)={T_i|$T_i \in$TDB, $T_i \supset X$} be the set of transactions containing itemset X, then we can have that:

$$ws(X) \sum_{T_i \in TDB_i} tw_i = \sum_{T_i \in TS(X)} tw_i. \quad (3)$$

For $Y \supset Z \supset X$, we have that $TS(X) \supseteq TS(Z) \supseteq TS(Y)$, then

$$\sum_{T_i \in TS(X)} tw_i \geq \sum_{T_i \in TS(Z)} tw_i \geq \sum_{T_i \in TS(Y)} tw_i. \quad (4)$$

From Equation (3), we can have:

$$ws(X) \sum_{T_i \in TDB_i} tw_i \geq ws(Z) \sum_{T_i \in TDB_i} tw_i \geq ws(Y) \sum_{T_i \in TDB_i} tw_i. \quad (5)$$

Then ws(X)≥ws(Z)≥ws(Y), and ws(Y)=ws(X), so ws(Y)=ws(Z) =ws(X), from definition 4, we have the lemma 3.

Lemma 4. For itemsets X, Y($Y \supset X$), ws(Y)=ws(X), then ∀ Z ($Z \supset X$, $Y \not\subset Z$), Z can't be a closed itemset.

Proof: For $Y \supset X$, $TS(X) \supseteq TS(Y)$, and ws(Y)=ws(X) in lemma 4, then TS(X)=TS(Y).From the property of set, we

can have TS(X∪Z)=TS(Y∪Z).Additionally, Z⊃X, Y⊄Z, we have

TS(Z)=TS(Y∪Z) and Y∪Z⊃Z,From the inference in lemma 3, we have that ws(Y∪Z)= ws(Z),Then we have the lemma 4.

From above lemmas, we can explore the weighted closed itemsets search space in specific manner, and can prune much search space early.

Theorem 1. All weighted association rules can be derived from weighted concise association rule based on closed itemset.

Rationale: Weighted support of any frequent itemset can be calculated by weighted closed itemset.

Proof: For any itemset X, there must be a weighted closed itemset Y⊃X, and ws(Y)=ws(X), otherwise from lemma 1, itemset X must be a weighted closed itemset. Thus we have weighted support of itemset X from itemset Y or X itself.

Then for any weighted association rule X⇒Y, there must be two itemsets V(V⊃X) and W(W⊃Y), that ws(V)= ws(X) and ws(Y)= ws(W). We can have support and confidence rule X⇒Y from rule V⇒W. Then we have theorem 1.

4 Enumerate weighted concise association rules

In this section, we try to enumerate weighted concise association rules while weighted closed itemsets are being mined. Several techniques are adopted to realize the process.

4.1 WEIGHTED CLOSED ITEMSET TREE

In this section, we arrange weighted closed itemsets in tree to decrease space occupation in weighted concise association rules generation. The tree is called weighted closed itemset tree (WCIT), which is like FP-tree. But items in the link from one node with weighted support to root form a weighted closed set while node without weighted support doesn't (Figure 1).

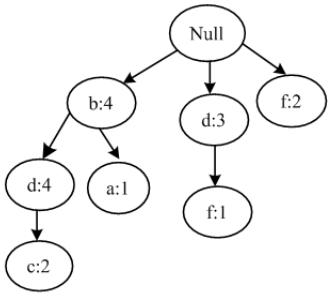

FIGURE 1 Weighted closed itemset tree

Then we have following property:

Property 1. One node without weighted support must have descendant nodes.

In the weighted concise association rules generation, we can index weighted closed itemsets or just candidate ones. If the tree is too large to be stored in memory, we can serialize it in external storage partially by branches.

4.2 MINING WEIGHTED CLOSED ITEMSET

In order to gear to mine the weighted concise association rules concurrently, we enumerate weighted closed itemsets in specific order.

We assume that there is a partial order on itemset I, denoted as $\prec$. Without loss of generality, we assume in the remainder of the paper $\prec$ is the ascending supports order of items in I. During the mining process, weighted closed itemsets will be enumerated according to partial order on itemset I. And duplicate search space will be pruned at the same time.

In this section, we exploit the conditional weighted closed set [21] to facilitate the mining process, which is denoted as CWCS($i_1,i_2,\ldots,i_k$), while following conditions are satisfied:

1) $i_k \prec \ldots \prec i_2 \prec i_1$;

2) $\forall X \in CWCS(i_1,i_2,\ldots,i_k)$ such that $\exists T \subset TDB$, $X \cup \{i_1,i_2,\ldots,i_k\} \subset T$;

3) Let i_m be the largest item in X, then $i_m \prec i_k$;

4) CWCS() is the conditional weighted closed set of ∅.

First, transactions' weights in database are calculated. Then they are projected into the conditional weighted closed set as the pattern grows.

Second, we initialize CWCS(). We eliminate all the items whose weighted support is less than ξ in all transactions and insert itemsets left into CWCS(). If there is a same itemset, then eliminate it and update weight of the other, otherwise initialize its weight. Then for every frequent item i_m in a CWCS($i_1,i_2,\ldots,i_k$), we do as follows: For every itemset t containing i_m in CWCS($i_1,i_2,\ldots,i_k$), we collect all the frequent item i_n in t where $i_n \prec i_m$, as a new itemset to be inserted into CWCS($i_1,i_2,\ldots,i_k,i_m$). Then we set CWCS ($i_1,i_2,\ldots,i_k$) to ∅. With the mining process recursively going on, all the conditional weighted closed sets are initialized.

But the weighted closed sets can be generated in different orders. We must choose one to facilitate weighted concise association rules generation. Generally the itemsets can be enumerated in depth-first order as following (Figure 2).

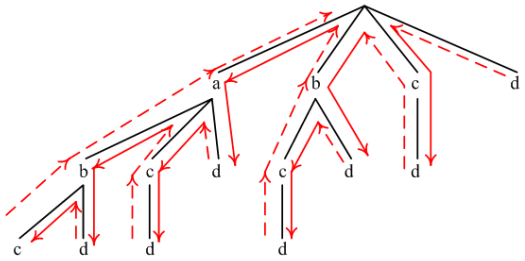

FIGURE 2 Itemset search space with four items

Itemset search space is traversed as following:

-{a}

-{b},{b,a}

-{c},{c,a},{c,b},{c,b,a}

We call it in right-depth-first order, in which latter items are always respected first, just as following:

-{d}

-{c},{c,d}

-{b},{b,d},{b,d},{b,c,d}

In right-depth-first mining process, the items nearer to root are always dealt with first. For an item i_n in CWCS $(i_1,i_2,\ldots,i_k)$, we assume all CWCS$(i_1,i_2,\ldots,i_k,i_m)$ $(i_n \prec i_m \prec i_k)$ have been dealt with, then for every i_m $(i_n \prec i_m \prec i_k)$, we do Weighted Checking (CWCS$(i_1,i_2,\ldots,i_k,i_n)$, CWCS$(i_1,i_2,\ldots,i_k,i_m)$).

After all items in CWCS$(i_1,i_2,\ldots,i_k)$ have been dealt with, we do as follows: for every item i_e in CWCS$(i_1,i_2,\ldots,i_k,i_n)$, i_e is inserted into every element of CWCS$(i_1,i_2,\ldots,i_k,i_n)$, then elements of CWCS$(i_1,i_2,\ldots,i_k,i_n)$ are removed to CWCS$(i_1,i_2,\ldots,i_k)$.

4.3 ENUMERATING WEIGHTED ASSOCIATION

In this section, we present the general mining method, which can generate weighted concise association rules while weighted closed itemsets are being enumerated as in Figure 3.

Through exploiting Weighted Checking technique and right-depth-first mining order, the proposed algorithm prunes itemset search space efficiently and integrates weighted closed itemsets and rules enumerating process properly [22,23].

For the given database and minimum support threshold ξ, all the weighted concise association rules based on closed itemsets can be get by calling procedure WeightedConciseRulesEnumerate () as following:

Procedure *WeightedConciseRulesEnumerate*(α)

(Here α represents $i_1,i_2,\ldots,i_k$ $(i_k \prec \ldots \prec i_2 \prec i_1)$)

Begin
Recalculate all weighted support(i) with the new occurrence frequencies in CWCS(α);
If (all support(i)< ξ)
{
Set CWCS(α) ={∅};
Return;
}
for item i=max to min contained in CWCS(α) do
{
if(support(i) ≥ξ)
{
project itemset in CWCS(α) to CWCS(α, i);
WeightedConciseRulesEnumerate (α, i);
for j=i+1 to max WeightedChecking(CWCS(α,i), CWCS(α, j));
}
}
if(there is an item i in CWCS(α) and support(α)= support(i))
Set CWCS(α)=RS(α)= ∅;
Else set CWCS(α) =∅;
RS(α)= {∅⇒{i}};
for(item i=max to min contained in CWCS(α))
{
for(every itemset is in CWCS(α,i))
Set CWCS(α)=CWCS(α)∪{is∪{i}} ;
Serialize Y={α,}∪is∪{i} into WCIT ;
For (every subset s⊂sY)
Generate rule s⇒sY with confidence ws(Y)/ws(X);
}
End.

4.4 WEIGHTED-SUFFIX-PROJECTION: MINING WEIGHTED CLOSED ITEMSETS DIRECTLY

When an item i_n is concerned, we can tell whether current itemset is closed by projecting larger items than i_n in its suffix link through adjusting its descendant linked branches. After all the descendant linked branches are combined, only the items with the same weight of item i_n are linked to its suffix link.

In the right-depth-first mining process, the larger items are always considered first. For items $i_3 \prec i_2 \prec i_1$, if ws(i_3) in CWCS(i_1) is equal to that in CWCS(i_1, i_2), item i_3 need not to be considered in CWCS(i_1). And item i_3 needn't to be projected on larger items in suffix links.

From above two main optimizations, we can just tell whether a weighted itemset I is closed through respecting the suffix of the minimum item in I. Additional calculation and space are not needed.

TID	items	*ws*
100	c,e	1.1
200	a,b,c,e	0.8
300	b,c,d	0.9
400	b,c	0.8
500	a,b	0.5
600	b,f	0.95
700	b,e	0.9
800	a,c,e	0.8667

item	*weight*	*support*	*ws*
a	0.4	0.375	0.3178
b	0.6	0.75	0.7115
c	1	0.625	0.6553
d	1.1	0.125	0.1320
e	1.2	0.5	0.5379
f	1.3	0.125	0.1395

FIGURE 3 Transaction database *TDB* and weight settings

Example 1. Given the transaction database TDB with the item weight settings, the minimum weighted support threshold ξ_1 =0.2 and confidence threshold ξ_2 =0.3, the created global FP-tree like structure is shown in Figure 4. Item e is removed for its support is below ξ. The ascending support order on I is $b \prec c \prec e \prec a \prec d \prec f$.

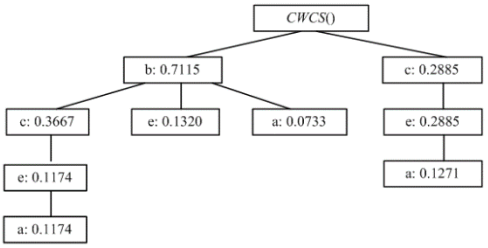

FIGURE 4 Data structure created for *CWCS*()

We can get following weighted closed itemsets as Figure 5:

-{a}:0.3178
-{b}:0.7115
-{c}:0.6533
-{e}:0.5379
-{b,c}:0.3667
-{b,e}:0.2494
-{c,e}:0.4059
-{c,e,a}:0.2445

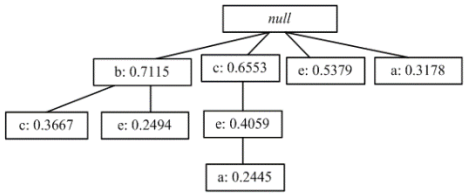

FIGURE 5 WCIT for generated concise itemsets

And we get weighted concise association rules based on weighted closed itemsets as following:

{b}⇒{b,c}:0.5154,
{c}⇒{b,c}:0.5154
{b}⇒{b,e}:0.3505
{e}⇒{b,e}:0.4637
{c}⇒{c,e}:0.6194
{e}⇒{c,e}:0.4637
{c}⇒{c,e,a}:0.3731
{e}⇒{c,e,a}:0.4545
{a}⇒{c,e,a}:0.7694
{c,e}⇒{c,e,a}:0.6024
{c,a}⇒{c,e,a}:1
{e,a}⇒{c,e,a}:1

We can see that the count of weighted concise rules is larger than that of weighted closed itemsets. After attaching weights to itemsets, the mining result is more reasonable in real applications than traditional ones. Additionally the number of useless concise itemsets and rules generated decreases greatly. And all general association rules can be derived from weighted concise ones.

5 Experimental results

In this section, we conduct experiments on public simulated data sets. The target platform is a Lenovo PC equipped with 2.6G clock rate CPU and 1024M main memory. The operation system is Windows XP Professional. The proposed algorithm is implemented in C++. The experimental data subsets include mushroom which contains all kinds of mushroom information with different properties which decide whether this kind of mushroom is poisonous, chess, pumsb, kosarak, T10I4D100K, Segmentation, etc. which can be downloaded from UCI Repository or Frequent Itemset Mining Implementation Repository [22].

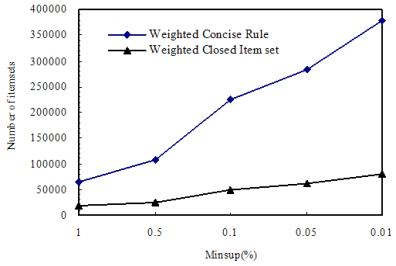

FIGURE 6 Size of rules and closed itemsets generated comparison

Here we carried out general association rule mining method and the proposed weighted concise association rule mining method in this paper under specific weights setting, selected size of rules and closed itemsets and runtime as assessment criteria. When attaching high weight to specific properties, the corresponding properties are more likely to be mined. Following Figure 6 and 7 show the experiment results.

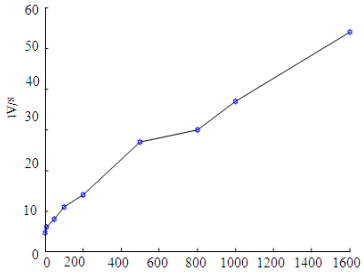

FIGURE 7 The saving time trend of the proposed weighted concise association rule mining

From above results, we can see that weighted concise association rules generation consumes no more time than just weighted closed itemsets generation only. But it can derive more reasonable result than traditional ones.

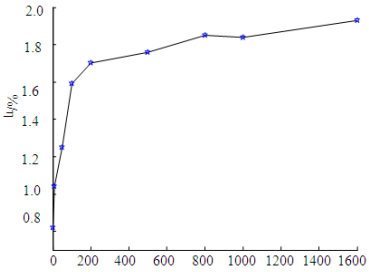

FIGURE 8 The saving time rate trend of the proposed weighted concise association rule mining method

From Figure 7 and 8,we can see that: when the data set size is bigger, the proposed weighted concise association rule mining method will save more time in constructing decision tree by contrast with the traditional one, thus the more efficient it is. Therefore, we can conclude that: in mining weighted concise association rules, the bigger the data set are, the more advantageous the proposed weighted concise association rule mining method is.

6 Conclusions

In this paper, we proposed a method for mining weighted concise association rules effectively. Based on specific search space exploring order, we gear rules generating process to itemsets exploring process properly, and derive all rules while enumerating closed itemsets concurrently. It can derive more reasonable results than general ones in real circumstance, but with less time consuming. The test results show that the algorithm has good time scalability.

Abstract

Scientific workflows are a topic of great interest in the Grid community that sees in the workflow model an attractive paradigm for programming distributed wide area Grid infrastructures. Scientific workflows have recently emerged as a new paradigm for scientists to formalize and structure complex and distributed scientific processes to enable and accelerate many scientific discoveries. In contrast to business workflows, which are typically control flow oriented, scientific workflows tend to be dataflow oriented, introducing a new set of requirements for system. In this paper, we consider a general workflow setting in which input data sets are processed by a graph of transformations to produce output results. Our goal is to perform efficient selective refresh of elements in the output data, i.e., compute the latest values of specific out-put elements when the input data may have changed. The data provenance is investigated to be used to enable efficient refresh. The proposed approach is based on capturing one level data provenance at each transformation when the workflow is run initially. Then at refresh time provenance is used to determine (transitively) which input elements are responsible for given output elements, and the workflow is rerun only on that portion of the data needed for refresh. The reported preliminary experimental results are developed on the overhead of provenance capture, and on the crossover point be-tween selective refresh and full workflow computation development.

Keywords: scientific workflows, scientific workflow management system, semantic technologies

1 Introduction

Scientific workflows have recently emerged as a new paradigm for scientists to integrate, structure, and orchestrate a wide range of local and remote heterogeneous services and software tools into complex scientific processes to enable and accelerate many scientific discoveries. Significant scientific advances are increasingly achieved through complex sets of computations and data analyses. These computations may com-prise thousands of steps, where each step might integrate diverse models and data sources that different groups develop. The applications and data might be also distributed in the execution environment. The assembly and management of such complex distributed computations present many challenges, and increasingly ambitious scientific inquiry is continuously pushing the limits of current technology.

Workflows have recently emerged as a paradigm for representing and managing complex distributed scientific computations, accelerating the pace of scientific progress. Scientific workflows orchestrate the dataflow across the individual data transformations and analysis steps, as well as the mechanisms to execute them in a distributed environment. Each step in a workflow specifies a process or computation to be executed according to the data flow and dependencies among them. The representation of these computational workflows contains many details required to carry out each analysis step developed within the context of an earthquake science application.

Workflow systems exploit these explicit representations of complex computational processes at various levels of abstraction to manage their life cycle and automate their execution. In addition to automation, workflows can provide the information necessary for scientific reproducibility, result derivation, and result sharing among collaborators. By providing automation and enabling reproducibility, they can accelerate and transform the scientific analysis process.

This traditional best effort execution model commonly does not fully consider the dynamic and course-grain nature of Grid environments dominated by a broad set of performance overheads such as large latencies (several seconds), unpredictable queuing times, sudden unavailability of existing resources, external load on shared-memory computers, unexpected jobs on shared local queues, and inaccurate predictions for new processor architectures, which can severely deteriorate the workflow execution that is likely to deviate from the expected schedules. In addition, although the Grid provides in theory an unlimited amount of compute power, currently existing Grid test beds offer a limited amount of high-performance resources that are important to be used efficiently.

Over the years, performance analysis tools have emerged as an important means for detecting bottlenecks in high performance computing applications for which optimizing compilers rarely deliver satisfactory results. Grid computing is sensitive to similar problems. Running workflows based on pure scheduling techniques without understanding what really happens during the execution

***Corresponding author** e-mail: buhuiemail@126.com

may easily lead to poor execution times and inefficient usage of computing resources. Performance analysis tools are there-fore an important asset for understanding the behaviour and reasons for performance losses required to improve runtime middleware environments and, ultimately, the workflow executions in dynamic Grid infrastructures. Such a tool for high-level performance analysis of scientific Grid work-flows is currently missing.

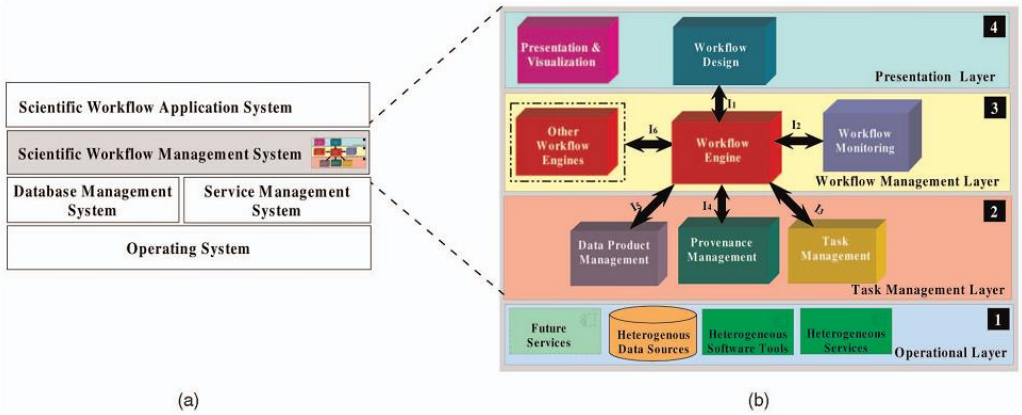

FIGURE 1 a) The position of an SWFMS within a software stack; b) zoom-in view of the reference architecture for SWFMSs

In this paper, we propose a systematic approach to building a tool for performance analysis and steering of scientific workflow applications in heterogeneous and distributed Grid environments. We introduce a theoretical reference parameter, called ideal execution time, that provides a realistic bound for the lowest (that is, "fastest") execution time achievable by a workflow in a certain Grid infrastructure. To address this issue, we propose the first reference architecture for SWFMSs based on a comprehensive survey of the literature and identification of key requirements. According to the proposed reference architecture, we further propose a service-oriented architecture for the VIEW system. Leveraging SOA, VIEW consists of six loosely coupled service components, each of which corresponds to a functional component that is identified in the reference architecture, whose functionality is exposed as a Web service. We implemented the VIEW system to validate the feasibility of the proposed architectures. We present a VIEW based scientific workflow application system (SWFAS), to demonstrate the capabilities of VIEW in support of user interaction intensive, visualization intensive, and compute intensive scientific workflows in a heterogeneous and distributed computing environment.

The rest of the paper is organized as follows. Section 2 identifies the related work of the proposed method. Section 3 proposes our reference architecture for SWFMSs. Section 4 we evaluate five representative SWFMSs using the proposed reference architecture. Finally, Section 5 concludes the paper and comments on future work.

2 Related works

Although the term "scientific workflows" were first coined by Vouk and Singh in 1996 [1] for workflow applications in scientific PSEs, only recently, there is an increasing momentum for the research and development of SWFMSs and their applications, due to the increasingly demanding requirements of many compute-intensive and data intensive scientific applications, enabled by the underlying advances of computing technologies, notably Services computing [2], Grid computing [3], and Cloud computing [4]. Scientific workflows leverage existing techniques developed for business workflows but deviate from them as a result of a different set of requirements raised from a wide range of science and engineering problems [5]. While business workflows are control flow oriented with the mission of carrying out business logic to achieve a business goal, scientific workflows tend to be dataflow oriented and aimed at enabling, facilitating, and speeding up the derivation of scientific results from raw data sets.

There has been a large body of work in lineage and provenance over the past two decades. Surveys are presented in, e.g., [6-8], and formal models for provenance are presented in, e.g., [9-12]. Provenance in the context of schema mappings is studied in [13-15]. None of these papers exploits provenance for selective refresh in a general workflow environment. There also has been a large body of work in incremental view maintenance: the efficient propagation of base data modifications, usually in a relational setting [16, 17]. Our work considers general workflows, rather than relational views. Also, in contrast to the view maintenance problem, selective refresh considers efficiently computing the up-to-date value of individual output elements, rather than keeping the entire view up to date by propagating changes made to the base data. Reference [18] provides a framework to explain "missing" answers in queries. There is some high-level

similarity between how explanations provided by their framework are created and how we support efficient refresh using data provenance. However, the details are quite different, and their framework supports SQL queries rather than general workflows. Reference [19] considers the problem of "update exchange" be-tween data peers linked by mappings. A problem they address is determining when a derived data element is no longer valid, but they do not provide a means to selectively refresh out-of-date values. Also, transformations in [19] are restricted to those that can be expressed in data log.

3 Incorporating semantic to data oriented workflow

Although the reference architecture proposed by WfMC, has been widely used for BWFMSs, this reference architecture does not satisfy key requirements R1-R5 for SWFMSs identified in the previous section. In this section we propose a reference architecture for SWFMSs. As shown in Figure 1b, the reference architecture consists of four logical layers, seven major functional subsystems, and six inter-faces. Figure 1a shows a typical software stack of a scientific workflow application: on top of an operating system, a data management system and a service management are used by an SWFMS for data management and service management, respectively. An SWFAS is developed over an SWFMS by the introduction of additional domain specific application data and functionalities.

3.1 DIFFERENT LAYERS OF THE PROPOSED METHOD

The first layer is the Operational Layer, which consists of a wide range of heterogeneous and distributed data sources, software tools, services, and their operational environments, including high-end computing environments. The separation of the Operational Layer from other layers isolates data sources, software tools, services, and their associated high-end computing environments from the scope of an SWFMS, thus satisfying requirement R5.

The second layer is called the Task Management Layer. Tasks are the building blocks of scientific workflows. Tasks consume input data products and produce output data products. At the same time, provenance is captured automatically to record the derivation history of a data product, including original data sources, intermediate data products, and the steps that are applied to produce the data product. This layer abstracts underlying heterogeneous data into data products, services, and software tools into tasks, and provides efficient management for data products, tasks, and provenance metadata. Therefore, the Task Management Layer satisfies requirements R2, R3, and R4. Moreover, the separation of the Task Management Layer from the Operational Layer promotes the extensibility of the Operational Layer with new services and new high-end computing facilities, and localizes system evolution due to hardware or software advances to the interface between the Operational Layer and the Task Management Layer. The task-level interoperability requirement (R7: level 1) should be addressed in this layer.

The third layer is the Workflow Management Layer, which is responsible for the execution and monitoring of scientific workflows. At this layer, the building blocks of a scientific workflow are the tasks provided by the underlying Task Management Layer. In this layer, an execution of a scientific workflow is called a workflow run, which consists of a coordinated execution of tasks, each of which is called a task run. Therefore, the Workflow Management Layer addresses requirements R6 and R7. The separation of the Workflow Management Layer from the Task Management Layer concerns two aspects as follows:

1) it isolates the choice of a workflow model from the choice of a task model, so changes to the workflow structure do not need to affect the structures of tasks and

2) it separates workflow scheduling from task execution, thus improves the performance and scalability of the whole system. The interoperability of workflows (requirement R7: level 2) has to be addressed by standardizing workflow models, workflow run models, and workflow languages.

The fourth layer is the Presentation Layer, which provides the functionality of workflow design and various user interfaces and visualizations for all assets of the whole system. The Presentation Layer has interfaces to each lower layer (not shown in the figure for simplicity). The separation of the Presentation Layer from other layers provides the flexibility of customizing the user interfaces of the system and promotes the reusability of the rest of system components for different scientific domains. Thus, this separation supports requirement R1. The interoperability of workflows (requirement R7: level 2) should be addressed by standardizing the workflow layout (e.g., look-and-feel) at this layer.

3.2 MIDDLEWARE OVERHEAD

The middleware overhead is due to the work performed by the middleware services to support the proper execution and completion of the workflow, which we further divide into several components based on the service functionality.

Resource brokerage. This represents the time required by the Resource Broker to query the information service and provide to the Scheduler the processors and activity deployments needed to execute the application. Addition-ally, this overhead has an important latency component (few seconds), mostly due to the mutual host authentication. This service latency is a common overhead component present in all our middleware services.

Performance prediction. This represents the time to provide forecast information about the execution time of individual activities on the Grid sites indicated by the Scheduler, for example, using a polynomial fitting heuristic based on historical or training data.

Scheduling. This represents the time to appropriately map the workflow activities onto the Grid resources, which includes the following two sub overheads:

1) a scheduling algorithm, which represents the time required to compute a schedule (often using time-consuming optimization heuristics if the scheduling problem is NP-complete), and

2) rescheduling, which represents the time needed to make a new scheduling decision, for example, because of a performance contract violation or if the workflow changes its runtime structure.

3.3 SUBSYSTEMS

The seven major functional subsystems correspond to the key functionalities required for an SWFMS. Although the reference architecture allows the introduction of additional subsystems and their features in each layer, this paper only focuses on the major subsystems and their essential functionalities.

The Workflow Design subsystem is responsible for the design and modification of scientific workflows. Workflow Design produces workflow specifications represented in a workflow specification language that supports a particular workflow model. One can design and modify a scientific workflow using a standalone or Web-based workflow designer, which supports both graphical- and scripting-based design interfaces. The interoperability of workflows (requirement R7: level 2) should be addressed in this subsystem by the standardization of workflow languages.

The Presentation and Visualization subsystem is very important especially for data-intensive and visualization-intensive scientific workflows, in which the presentation of workflows and visualization of various data products and provenance metadata in multi-dimension is the key to gain insights and knowledge from large amount of data and metadata. These two subsystems are located at the Presentation Layer to meet requirement R1. In this subsystem, the interoperability of workflows (requirement R7: level 2) should be addressed by the standardization of scientific workflow layout.

The Workflow Engine subsystem is at the heart of the whole system and is the subsystem that provides management and execution environments for workflow runs. The Workflow Engine creates and executes workflow runs according to a workflow run model, which defines the state transitions of each scientific workflow and its constituent task runs. The interoperability of workflows (requirement R7: level 2) should be addressed by the standardization of interfaces, workflow models, and workflow run models, so that a scientific workflow or its constituent subworkflows can be scheduled and executed in multiple Workflow.

Engines that are provided by various vendors. In SWFMSs, multiple Workflow Engine subsystems can be distributed, and each Workflow Engine can execute several workflows in parallel.

The Workflow Monitoring subsystem meets requirement R6 and is in charge of monitoring the status of workflow execution during workflow runtime and if failures occur, provides tools for failure handling [18].

The Task Management subsystem addresses heterogeneity and distribution issues (requirement R3) and provides management and execution environment for tasks, according to a task model and task run model, respectively. The interoperability of tasks between various workflow environments (requirement R7: level 1) can be addressed in this subsystem.

The Provenance Management subsystem meets requirement R2 and is mainly responsible for the management of scientific workflow provenance metadata, including their representation, storage, archival, searching, and visualization. The Data Product Management subsystem meets requirement R4 and is mainly responsible for the management of heterogeneous data products. One key challenge for data product management is the heterogeneous and potentially distributed nature of data products, making efficient access and movement of data products an important research problem. The interoperability of data products between various workflow environments (requirement R7: level 1) can be addressed in this subsystem.

3.4 SYSTEM PROTOTYPE

We have built a prototype system that implements all features and algorithms presented in this paper. This system, built initially to support refresh, has been evolving into a more ambitious sys-tem we call Panda (for Provenance and Data), supporting several other aspects of provenance and data in addition to refresh [17].

In this paper we focus our system description on features relevant to refresh. For the time being, all data sets handled by Panda are encoded in relational tables, but as we have seen, our formal under-pinnings and algorithms do not rely on the relational model. The high-level architecture of the Panda system. The main backend is a SQLite server, storing all data sets, relational (SQL) transformations, provenance, and workflow information. The Panda system supports “opaque” transformations programmed in Python; they are stored separately in files.

Users interact with Panda through a simple command-line inter-face; we intend to build a GUI in the near future. There are three types of user commands:

1) Creating or modifying input data sets;

2) Creating transformations that generate newly-defined data sets from existing ones, to build up workflows;

3) Refresh commands.

The Panda Layer processes all user commands: it stores workflow graphs and their transformations, creates and maintains auxiliary provenance tables, generates provenance predicates and forward filters for output elements, and runs the refresh algorithms.

The Panda system also supports transformations specified as SQL queries, including

queries/transformations involving multiple input tables. Provenance predicates are created automatically for SQL transformations, following known definitions and techniques [5, 7, 10]: Single table Select statements are one-one, so their output provenance predicates can select on declared keys from the input data set. Multi-table Select statements generate provenance predicates for each input table separately, again relying on declared keys. Finally, Group-by queries generate provenance predicates based on the grouping attribute(s). The command to create a new SQL transformation is similar to the command shown in Section 8.1, except followed by a SQL query, whose from clause must refer to already-defined tables. The steps performed by the Panda Layer are also similar to those outlined in Section 8.1; forward filters are never needed since SQL queries cannot produce many-many transformations.

When workflows are created and run, Panda stores everything needed to support selective refresh: provenance predicates and intermediate data sets for backward tracing; transformations and forward filters for forward propagation. The Panda system assumes that all transformations, provenance, and workflows satisfy the requirements specified in this paper. Automatically detecting when the requirements are satisfied—particularly the most interesting requirement of workflow safety is an important area of future work. Under the assumption of all requirements being satisfied, Panda supports selective refresh using the exact algorithms given in this paper.

4 Experimental results

We implemented our approach as a distributed online performance analysis tool within the ASKALON programming and computing environment for the Grid. We implemented P-C and P-SC correlators in Python as WSRF-compliant Web services exposing all unprocessed events as reference properties. We translate our formal rule correlation algebra to a lower level open source correlation engine called the Simple Event Correlator.

We employ the PyGnuplot module that is a Python wrapper to the Gnuplot program to display two different kinds of execution graphs in real time, as presented in this section. We describe experiments of applying our tool for online analysis of the main overheads, using the WIEN2k workflow. We chose a problem case that we solved using 193 parallel k-points and a problem size of 8.5, which represents the number of plane waves that is equal to the size of the eigenvalue problem (that is, the size of the matrix to be diagonalized).

We created three groups of peers, one for each city location. The group in Innsbruck consists of four P-Cs and one P-SC, whereas in Linz and Salzburg, we only started one P-SC as we only had one Grid site available. We elected the Innsbruck P-SC as the coordinator.

The first histogram in Figure 2 illustrates a generic technique that we use to represent the major online phases that occur during the workflow execution. We defined for all overheads a performance contract membership function with a low step threshold that generates a contract variable with a critical value at every polling instance (we disabled the rescheduling action). The horizontal line indicates the overhead that holds at any execution instance, whereas the vertical lines are drawn for readability purposes only. The histogram shows that at the beginning of the execution, we experienced some delay due to the operations performed by the middleware services, more precisely the Resource Broker to retrieve the list of available Grid sites and the Scheduler to compute the mapping of the workflow onto the Grid sites. One characteristic of this workflow is that the number of activities in the parallel regions is unknown until the first activity completes its execution. Since this cardinality port is statically unknown, the Scheduler assumed one activity in each case and serialized all workflow activities onto one Grid site. After another preparatory step to create remote directory structures required to run the legacy applications that implement the workflow activities, the Enactment Engine submitted the first activity and therefore added some queuing overhead. After this first activity completed, the output files were broadcasted to all sites, which added a small data transfer overhead.

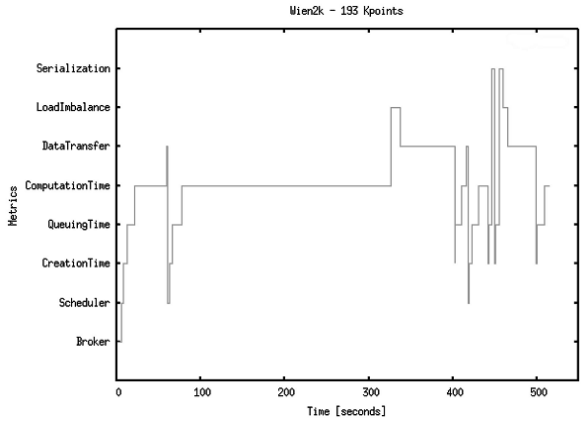

FIGURE 2 Online overhead histogram

After the cardinality port was instantiated, a rescheduling event was triggered upon contract violation, and the Scheduler mapped the new workflow onto the Grid using the Heterogeneous Earliest Finish Time heuristic which added a corresponding overhead. Thereafter, all 193activities were submitted in parallel, since the number of processors available on the Grid test bed was large enough to accommodate them. Since our Grid contains heterogeneous processors, some of the activities completed before the others, which produced a slight load imbalance. As lapw1_k is the most time-consuming activity type of the workflow, we did not experience any significant overhead during this phase, which means that the workflow was performing a useful computation. After this positive execution phase, a large number of files had to be gathered onto one single site where a small activity

called lapp1_fermi processed them, which caused a rapid increase in the severity of the data transfer.

Figure 3 depicts another online-generated histogram that represents the aggregated severity of each analysed over-head at every time instance during execution. The last four sites in our Grid test bed are workstation networks that are automatically restarted in Linux Grid mode during night, weekend, and public holidays and are manually rebooted by students and lecturers during the weekdays in Windows mode for their laboratory classes when they are no longer available for our Grid experiments. After this first positive phase in the workflow execution, we decided to exploit the dynamic characteristic of our Grid test bed and removed the availability of the last four Grid sites by manually turning off the workstations that run the GRAM gatekeepers. This eliminated 51 per cent from the total number of available processors, and as a consequence, the Resource Broker created an appropriate event signalling that at time instance, an important number of computational resources had been lost. The arrival of the (simplified) event and, therefore, the serialization overhead, which indicated that some of the lapw2_k parallel activities had to wait in the queue and were executed sequentially due to the lack of available Grid sites.

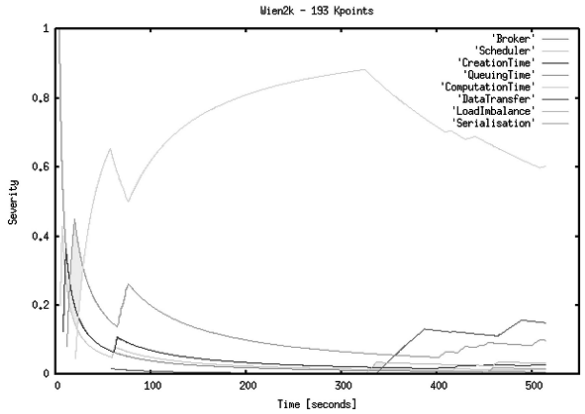

FIGURE 3 Online overhead severity histogram

Our tool is able to automatically generate real-time graphs that represent the chain of events that led to this serialization overhead using the Pydot wrapper to the GraphViz program, as illustrated in Figure 4. At the same time, our tool can automatically produce an online over-head correlation tree for any workflow region at any execution instance. Figure 5 shows this tree for the workflow region indicating that 76.6 per cent of its time is due to the total identified overhead, which is further split into five overheads: queuing, load imbalance, job preparation, data transfer, and serialization, each of them with its own severity value.

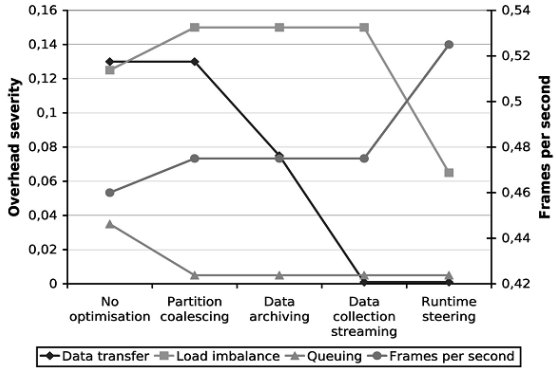

FIGURE 4 Overhead severities for various optimizations.

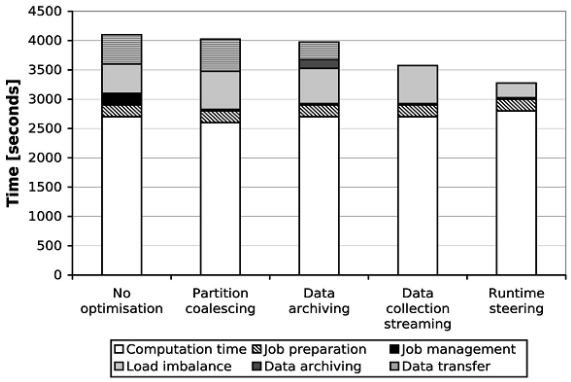

FIGURE 5 Runtime comparison for various optimizations

6 Conclusions

In this paper, we presented a systematic analysis model consisting of a theoretical ideal execution time and a detailed hierarchy of overheads that help the application developers understand the sources of bottlenecks that affect the distributed execution of scientific workflows in heterogeneous Grid infrastructures. We carefully defined the overheads to be as little overlapping as possible, which gives us an important indication of whether any performance loss remained unidentified. We adjusted well-known normalized metrics from parallel processing to the Grid computing scope, including overhead severity, speed-up, and efficiency, which are invaluable parameters to be considered before scheduling when the efficient use of resources is an important issue.

We implemented our approach as a distributed online performance analysis tool within the Grid programming and computing environment. We proposed a distributed super architecture for performance analysis, in which individual peers local to Grid sites correlate large numbers of events to find small sets of meaningful overheads at a higher level of abstraction. To the best of our knowledge, this is the first attempt of applying the event correlation technology, highly successful in the networking field, to the performance analysis of workflow applications in Grid environments. Additionally, we extended the current best effort practice in executing scientific Grid workflows by

defining performance contracts as QoS parameters to be enforced during execution through event-correlation-based fuzzy logic rules. We illustrated experiments for the postmortem and online analysis of two real-world workflow applications with a dynamic structure (that is, statically unknown before the execution) in a real and dynamic Grid environment. The postmortem analysis presents the advantage of detail and rigor through repetitive executions and measurements, whereas the online analysis is invaluable for runtime adaptation, QoS enforcement, and steering. We learned that the serialization of independent activities, load imbalance, job preparation and management, and transfer of large numbers of data dependencies are the most severe overheads for our case-study applications that have to be carefully tuned for achieving good speedup and the efficient use of Grid resources. In this context, we introduced several generic optimization and tuning techniques including workflow partitioning, data archiving, data collection streaming, and runtime steering

A boundary knowledge field based data mining method

Shan Feng*

School of Computer Science and Technology, Hubei Polytechnic University, China

Received 1 March 2014, www.cmnt.lv

Abstract

Data mining (the analysis step of the "Knowledge Discovery in Databases" process, or KDD), an interdisciplinary subfield of computer science, is the computational process of discovering patterns in large data sets involving methods at the intersection of artificial intelligence, machine learning, statistics, and database systems. Knowledge is the source of getting and keeping the strength of competence, knowledge becomes an important strategic resource at the age of knowledge economy. The way to facilitate knowledge transfer smoothly plays a critical role in determining the competence of an organization or organizational system. To explore the mechanism of knowledge transfer, the characteristics of sticky transfer (flow) is compared with the flow characteristics of viscous fluid, and the knowledge on the theories of field in physics, viscous fluid mechanics and boundary layer is employed and analysed in this paper. Firstly, the concept of boundary layer in the knowledge field is proposed to analyse the difference of knowledge stickiness in the knowledge field and describe the contradictory relationship between knowledge stickiness and liquidity. Secondly, based on the analysis of the knowledge transfer in the boundary layer, the dynamic mechanisms of sticky knowledge transfer are analysed from the three aspects of the knowledge potential difference force, the viscous force and the extern driving force. The rotation mechanism of knowledge in the knowledge field is discussed, and the dynamic model of the boundary layer of knowledge field is built. Finally, the phenomenon of knowledge flowing into and flowing out of boundary layer is discussed, and the knowledge transfer conservation equation in the boundary layer is constructed to describe the updating and appreciation of knowledge in the boundary layer of knowledge field.

Keywords: data mining, knowledge transfer, knowledge field, boundary layer

1 Introduction

The overall goal of the data mining process is to extract information from a data set and transform it into an understandable structure for further use. Aside from the raw analysis step, it involves database and data management aspects, data pre-processing, model and inference considerations, interestingness metrics, complexity considerations, post-processing of discovered structures, visualization, and online updating. Knowledge is distinguished from data and information. The data is organized to produce general information [1], and information has little value in itself until it becomes knowledge as a result of processing by the human mind [2]. For knowledge, it involves a person using his or her perception, skills and experience to process information - thus converting it into the knowledge in the mind of the individual [3]. Knowledge is a vital source for the organizations to gain the advantage in the competition [4]. Ever since the conception of knowledge economy is brought forward by Drucker [5]. The position of knowledge in the development of economy is increasingly gaining more and more attention, and researches have shown that the world economy is driven by the production, transfer, and use of knowledge [6, 7]. In the time of knowledge economy, knowledge transfer and creation are growing more and more important, no matter for individuals, organizations, or even countries [8, 9]. Taking its fluidity into consideration, knowledge is considered to be one fluid and it can transfer among organizations. Therefore, the concept of knowledge transfer is propounded by Teece [10]. He pointed out that it is a process in which knowledge is sent and received back and forth between knowledge senders and receivers [10]. Knowledge transfer is a communication process in which knowledge flows between demanders and producers [11]. It is an important factor for an organization's success [12]. Accordingly, many studies analyzed the factors that affect knowledge transfer, and showed that the knowledge characteristics, such as tacitness, expressiveness and complexity, directly change the process of knowledge transfer (Szulanski, 1996; Zander, 1991; Simonin, 1999) [13-15]. Afterwards Cummings and Teng [16] studied the influences of the expressiveness and embedded-ness of knowledge on knowledge transfer. Then Ajmal & Koskinen (2008) [1] elaborated the knowledge transfer from three perspectives: first, as a solution, knowledge emphasizes the real-time transfer of knowledge among practitioners who are seeking to solve problems or enhance operations; second, as an experience, knowledge describes the progressive process of acquisition and accumulation for the possible use in the future; third, as a social product, knowledge is created and shared through interpersonal relationship and social network.

Due to the fact that knowledge transfer is an essential role for the organizations to gain the advantage in the

***Corresponding author** e-mail: shanfenghbpu@126.com

competition, it is very important to accurately describe the transfer mechanism of knowledge in an organizational system [17, 18]. Since the concept of knowledge field (Ba) was proposed by Nonaka and Takeuchi in 1995 [19], the concept gave researchers lots of inspiration on knowledge transfer. Nonaka and Takeuchi [19], additionally, structured the SECI model of knowledge transfer and creation, meanwhile they pointed that knowledge field could provide energy for knowledge transfer and creation and affect the quality of knowledge production. Based on the SECI model of knowledge creation, Ba, which is conceptualized as a shared context in motion, can transcend time, space, and organization boundaries to create knowledge [20]. The theory of knowledge field is widely recognized [21, 22]. Against this background, many researchers have conducted deep research on the transfer mechanism of knowledge based on the concept of "knowledge field". The process and the influence factors of knowledge transfer (flow) are analysed [23, 24]. The view of Nonaka is accepted by Eastern researchers, but the Western pay attention to research the process of knowledge share and based on the organizational theory and the social capital theory analyse the construction of communities of practice and the impact of the knowledge-sharing field (communities of practice) on the organizational performance [25-27].

Throughout the above researches, the knowledge transfer (knowledge flow) and knowledge stickiness have been analysed, which attempt to explain the mechanism of knowledge transfer and the influence mechanism of the stickiness on knowledge transfer. However, most of these investigations mainly focus on qualitative discussion and empirical analysis based on questionnaires. Since the mechanism of knowledge transfer is still not fully understood, there remains a lack of systematically theory and mathematical model to elaborate the process and mechanism of knowledge transfer. As discussed earlier, it is known that knowledge has the properties of stickiness and field. In fluid dynamics, when the fluid flows in the flow field, it has the properties of liquidity and stickiness which make the phenomenon of the boundary layer generated [45, 46]. In 1904 it is the great achievement of Ludwig Prandtl who set forth the concept of boundary layer at the Heidelberg mathematical congress. Prandtl showed that the flow past a body can be divided into two regions: a very thin layer close to the body (boundary layer) where the viscosity is important and the remaining region outside this layer where the viscosity can be neglected [47]. It is confirmed that the appearance of the boundary layer phenomenon is caused by the liquidity, the viscosity and the properties of field. It should be mentioned that knowledge also has these properties in the process of knowledge transfer (flow). It is believed that the mechanism of knowledge flow (knowledge transfer) is similar to that of viscous fluid flow.

Therefore, the study is inspired by viscous fluid mechanics, and the viscous fluid-flow model and the boundary layer theory is employed to describe the process of knowledge transfer in this article. The flow of the sticky knowledge in the knowledge field is explained by the phenomenon of the boundary layer. On this basis, the rotation of knowledge field through the boundary layer phenomenon of knowledge stickiness is analysed. Meanwhile, based on the partial differential theory and the analogy method of viscous fluid dynamics, the dynamic equation and conservation equation of knowledge field are derived in order to analyse the dynamic mechanism of knowledge transfer under the action of different effects and the updating and appreciation of knowledge in the boundary layer of the knowledge field.

2 Boundary layer model of knowledge transfer

In a great deal of previous researches, knowledge transfer is widely recognized as an essential process in which an organization can acquire valuable knowledge to produce knowledge and boost economic performance [28-31]. However, organizational members in their own interest are unwilling to share core information they possess with other members [32]. Thus, it is difficult to effectively achieve the transfer of knowledge among different organizations [14, 33, 34], even among the different departments in an organization. This is, to a large extent, because knowledge has stickiness which severely hinders the transfer of knowledge between knowledge providers and knowledge users [34-36]. The knowledge stickiness can be defined as the extent to which knowledge is unremovable from its originating source [37]. A series of investigations on knowledge stickiness have been conducted by many researches [38-40]. Knowledge stickiness comes from the concept of "sticky information", which was introduced by Von Hippel [38] to describe information that is difficult to transfer. On this basis, Szulanski [14] extend the concept of information stickiness and defined knowledge stickiness as difficulties encountered in the process of knowledge transfer. The above knowledge which is hard to transfer is called sticky knowledge, and it is hard to transfer smoothly than general knowledge (namely, its stickiness is negligible). And then researches have further explored how properties of knowledge influence the transfer of sticky knowledge. Simonin [15] analysed the phenomenon of stickiness in the process of knowledge transfer from the aspects of tacitness, assets specificity, complexity, protection of its owners, cultural and organization distance etc. The "causal ambiguity" of the knowledge or the extent to which it was not well understood predicted the difficulty of transfer throughout all phases of the transfer process [4]. According to the process of knowledge transfer (initiation, implementation, ramp-up and integration), Szulanski [41] also discussed the nature of difficulty caused by stickiness at each stage.

When acknowledged, knowledge can be categorized into tacit knowledge and explicit knowledge [19], the stickiness of tacit knowledge is greater than that of explicit knowledge, and the transfer of tacit knowledge is more difficult. Thus, simple, codified knowledge is easier and

more efficient to transfer than complex, tacit knowledge among members in organizations, and meanwhile to strengthen members' tie can increase the ease and efficacy of transferring complex, tacit, and private knowledge [42, 43]. According to the research of Szulanski and Cappetta et al [44], knowledge stickiness means the difficulty of intra-organization knowledge transfer, and it can weaken the organizational flexibility and reduce the capacity of making full utilization of the knowledge which transfers between the enterprise and its partners. Thus, for an organizational system, the way to transfer the sticky knowledge smoothly plays an important role in improving the efficiency of innovation and keeping strength of competence.

Knowledge has the properties of field, and its distribution is uneven in time and space. In the knowledge field, the potentials of knowledge owners are related to the knowledge stocks that they own, that is, the more knowledge stocks they have, the higher knowledge potential they locate (Wang, Xing & Tang, 2010) [22]. Driven by the fluidity and inhomogeneous distribution of knowledge in the knowledge field, knowledge flows from the area with higher knowledge potential to the area with lower knowledge potential [24], which makes the knowledge providers interacting with knowledge users. In the interacting process, the share, transfer, and production of knowledge are conducted. However, because of its stickiness, knowledge fails to transfer smoothly, namely there are obstacles during the process of sticky knowledge transfer [36, 48, 49].

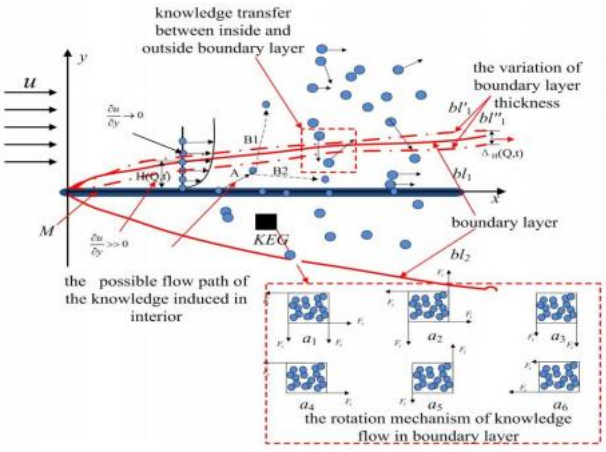

FIGURE 1 Boundary layer model of knowledge transfer

To describe the process of sticky knowledge transfer and to characterize the mechanism of knowledge transfer, the boundary layer model of knowledge field is established when sticky knowledge flows between knowledge providers and knowledge users in the knowledge field. To simplify this model, a two-dimensional knowledge field is employed to describe the boundary layer phenomenon of knowledge field, as the Cartesian coordinate of X-O-Y shown in Figure 1.

In Figure 1, we suppose that the blunt body M represents an organization in the knowledge field, and there is a variety of knowledge in the two-dimensional knowledge field. The circular marks indicate a variety of knowledge that the organization has in the knowledge field. The size of circles mark indicates the stock of one type of knowledge, and the arrows for the circle marks represent the direction of knowledge motion in the knowledge field. The circle marks is also called one knowledge unit in this paper, which is so small that it cannot be divided. Different knowledge units have different speeds. Some knowledge units can almost transfer freely in the knowledge because of the tiny sticky, some may not transfer smoothly and even the speed of it is near zero due to the strong viscous resistance. The speed of knowledge transfer in the knowledge field is expressed in u. According to the viscous fluid dynamics theory, the phenomenon of boundary layer will be produced near the surface of an object, when viscous fluid passes the surface of an object at a certain speed [46, 50]. Similarly, due to the stickiness of knowledge, it is believed that, when knowledge flow around an organization in the knowledge field, the phenomenon of the boundary layer will appear near the organizational boundary. The phenomenon of the boundary layer in the knowledge field is referred to as the boundary layer of knowledge field in this paper. As shown in Figure 1, the knowledge field is divided into two regions: the knowledge field inside the boundary layer and outside the boundary layer. The knowledge field inside the boundary layer is the area between the red solid line bl1 and bl2, and the other area is the knowledge field outside the boundary layer. Similar to the theory of fluid mechanics [51], the effect of stickiness on the knowledge field inside the boundary layer is so great that the velocity gradient of knowledge transfer is very large, and the velocity near the areas of the surface of an object (the object is M in Figure 1) tends to zero. That is, the effect of the stickiness of knowledge on knowledge transfer in boundary layer is significant, and the stickiness of knowledge inside boundary is not ignorable. However, the stickiness of knowledge outside the boundary layer is small, and even it can be ignored, it is approximatively considered that knowledge in the area is in the free-flow state without viscous force. It is known that with the value of knowledge increasing, the will of share becomes weak and the difficulty of knowledge transfer increases. Therefore, it is believed that the magnitude of the stickiness is directly related to the value of knowledge. In the current discussion, the knowledge in the knowledge field is divided into two categories according to its value or importance: sticky knowledge and general knowledge. Sticky knowledge is usually core and important knowledge for an organization, and general knowledge is not core knowledge and can be obtained freely, and its stickiness is small.

In the previous studies, there are arguments that knowledge field is rotational or not. Some researchers suggested knowledge field is rotational [23, 24, 52], and

others believed that knowledge field is irrotational or did not considered the rotation of knowledge field [22, 53]. According to viscous fluid mechanics, the area inside the boundary layer is the rotational area due to the stickiness of fluid in the flow process [54]. However, owing to the tiny viscous shear force, the rotation of flow field outside the boundary layer is negligible; namely, the area outside the boundary layer can be considered to be irrotational area [54]. Similarly, it is believed that knowledge field is rotatable owing to the knowledge stickiness. Due to the fact that the stickiness of knowledge outside boundary layer is small, the rotation of knowledge field outside boundary layer is small and even negligible. However, inside the boundary layer, the rotation of knowledge field is large because of the large stickiness of knowledge. That is, the knowledge field inside boundary layer is rotational, and the knowledge field outside boundary layer is irrotational. To clearly show this point, the microscopic subunit inside the boundary layer of knowledge is called knowledge element group (KEG) in this paper, as shown in Figure 1. In the microscopic subunit, there are interactions between different kinds of knowledge under the influence of strong viscous force. As the stickiness of each kind of knowledge in the knowledge element group is different, and the level and the direction of the viscous shear force on the different boundary of knowledge element group are also different, so the phenomenon of the rotation occurs under the action of viscous shear force. The six rotation situations caused by the viscous shear force with different levels and directions on the boundary of KEG are illustrated, as the marks a shown in Figure 1. Whereas, when the KEG is located outside boundary layer, the interactions between the different kinds of knowledge in KEG under the influence of viscous force is tiny, and the situation which is similar to the interaction between ideal inviscid gas molecules exists only in KEG. Meanwhile, the viscous shear force on the boundary of KEG is also tiny. Therefore, the rotation of knowledge field outside boundary layer is tiny and even negligible.

3 The dynamic model of knowledge transfer

The blunt body M on the x axis represents an organization in the knowledge field, which is the same as the Figure 1. In Figure 2, BC shows the boundary line of the boundary layer; represents the velocity of knowledge transfer in the boundary layer; H expresses the thickness of boundary layer at x=x0, and H1shows the thickness of boundary layer at x=x1. The variable dH shows that the variation of thickness when x changes the distance of dx.

The variables Fp, Fτ and Fe are the powers in the direction of x which represent the knowledge potential difference force, the viscous force and the extern driving force, respectively. The knowledge potential difference force, the viscous force and the extern driving force are caused by the knowledge potential difference, knowledge stickiness and the extent of the external driving, respectively. To analyse how sticky knowledge transfers under the interaction of internal and external force in the boundary layer, the dynamic model of sticky knowledge transfer is built, as shown Figure 2.

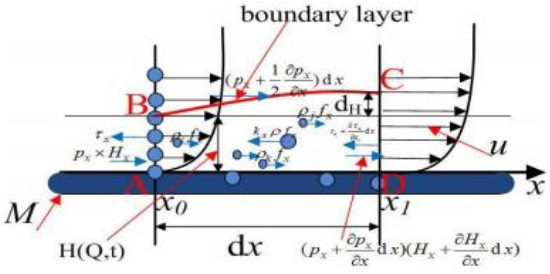

FIGURE 2 The dynamic model of knowledge transfer

Finally, to clearly describe the dynamic model of the boundary layer of knowledge field, the example of the supplier management of Japan's Toyota Motor Corporation is employed.

In the knowledge field, it is believed that the knowledge transfer in the boundary layer is mainly influenced by the three forces:

(i) Due to the difference of knowledge stocks among organizations, knowledge pressure (similar to water pressure and the voltage) is caused, and then the first field force, that is, the potential difference of knowledge force that lead to knowledge flow is generated [22, 56].

(ii) The influence of knowledge stickiness on knowledge transfer and sharing causes the second field force, namely the viscous force [36, 37].

(iii) The organizations within and outside the knowledge field, such as government and core enterprise, can make scientific incentive mechanisms to promote knowledge sharing and flowing.

Thus, the third field force is caused, which is referred as the external force [57, 58]. Under the joint action of the above three field forces, all kinds of knowledge unit in the knowledge field will move directionally.

The case of Japan's Toyota Motor Corporation is also introduced to discuss the sticky knowledge transfer in knowledge field. Japan's Toyota Motor Corporation (hereafter, referred to as simply Toyota) was founded in 1933, which is the biggest car company in Japan and world's top ten car companies, and it plays an important role in the world's auto industry. The success of Toyota to some extent comes from effective supplier management way. Toyota pioneered the management style of knowledge sharing among suppliers, which has had some great effects on supplier management, and has been adopted in many other companies. Toyota has always attached importance to its cooperation with suppliers, and it and 270 suppliers form a knowledge field by cooperation, in which the knowledge stocks of Toyota and its suppliers is significantly different, so there are the potential difference forces (Fp) prompting sticky knowledge transfer among Toyota and its suppliers. With the above force, Toyota would open and share sticky knowledge that can help suppliers improve productivity, and the suppliers also share their sticky knowledge with Toyota and others

so that suppliers and Toyota grow together through their mutual cooperation. Nevertheless, given their own interest consideration, suppliers are reluctant to share their core knowledge inside the boundary layer to others, so the transfer of the core knowledge in the knowledge field is hindered. The above core knowledge is called sticky knowledge, such as patents and core technologies. Generally speaking, the transfer of patents and core technologies is purchased at the expense of equal knowledge or cost of the users. The value of the equal knowledge or cost can be considered as the viscosity of the transferred knowledge. The force generated by sticky knowledge (Fτ) has the reverse force on the knowledge transfer.

Due to the viscous force, it is difficult to achieve sticky knowledge transfer smoothly in the knowledge field. Therefore, to be successful in implementing sticky knowledge transfer according to the wishes of the core organization (Toyota), some policies (Fe) should be introduced by Toyota to drive high efficiency knowledge transfer. For this, Toyota formulated two efficient governance mechanisms which is respectively reputation and commitment mechanism to make suppliers share their own core knowledge to others, as follows:

(i) During the process of cooperation, if the supplier positively shares the core or valuable knowledge (sticky knowledge) with others in the knowledge field, his reputation will be raised, and Toyota will offer more valuable technology or knowledge to him. Otherwise, if the supplier only obtains valuable knowledge from others in the knowledge field but is not reluctant to shares his own core knowledge or valuable knowledge (sticky knowledge), his reputation will be reduced, and Toyota will not offer key technology or knowledge to him and even break up the partnership.

(ii) Since the suppliers fear that their interests will be hurt when they share their core knowledge with others, Toyota establishes commitment mechanism to protect their interests.

This is, Toyota makes the commitment that the orders of the above suppliers will be increased and the supply prices will not be also raised due to their higher productivity within 2 to 3 years. Therefore, under the combined action of Fp, Fτ and Fe in the knowledge field, Toyota and its suppliers successfully achieve the goals of mutual cooperation, promotion and common development.

4 The conservation model of knowledge transfer

To describe the variation of knowledge stocks in the process of knowledge transfer in the boundary layer, the research object M is also employed, as shown in Figure 3.

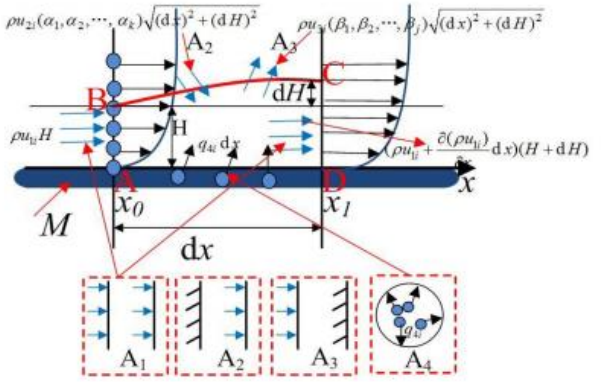

FIGURE 3 The conservation model of knowledge transfer

The blunt body M and BC represents an organization in the knowledge field and the outer horizon of the boundary layer, respectively; ui, H, H1 and dH represents the speed of knowledge transfer in the boundary layer, the thickness of boundary layer on the x0 points, the thickness of boundary layer on the x1point and the variation of thickness is caused as the point in the direction of x changes the distance of dx, respectively. The above is the same as the Figure 2.

In the boundary layer of knowledge field, the sticky knowledge of organizations do have is not to be constant, which flows constantly among organizations in the knowledge field. According to fluid dynamic theory, for a research object, generally speaking, if it has inflow variables, it also has outflow variables. Analogously, for the research object M in the boundary layer of knowledge field, the inflow variable on the boundary AB can be written as shown in Figure 3.

Unlike the flow dynamics, there are the other three ways due to knowledge specific attributes in the knowledge field, as the marks A2, A3 and A4 shown in Figure 3. From the mark A2, it has outflow variables but no inflow variables in the boundary layer. For example, when participating in the league and cooperation, the organization, in the knowledge field, shares its core knowledge (namely, the sticky knowledge) with others, but the spill over effect of the knowledge which is absorbed from others in the organization is not obvious because of the organization's low learning, low absorbing knowledge ability and low efficiency of utilizing knowledge gained from others. Thus, there might be a situation where the organization only shares core knowledge but not obtain valuable knowledge from the knowledge field. The process of knowledge transfer is achieved by overflowing the boundary of the boundary layer in the knowledge field. It should be mentioned that new knowledge will be created due to the novel combination of existing knowledge [61]. The extent to which actors can efficiently search for, access, transfer, absorb, and apply knowledge influences their ability to create knowledge [62, 63]. Another case is that new knowledge created by an organization itself is be stored in

the boundary layer and does not outflow the boundary layer, as the mark a4 shown in Figure 3.

As analysed above, we know that the variation of the thickness of boundary layer (the knowledge stocks of boundary layer) is characterized by the knowledge flow conservation equation in the boundary layer. The thickness of boundary layer of the knowledge field for each organization is dynamic, which changes with time and location. The factors, such as knowledge transfer between inside and outside boundary layer, knowledge creation, and usefulness of knowledge declining, can cause the variation of boundary layer thickness. Meanwhile, knowledge transfer should be in relative balance situation under the action of the function and mechanism in the boundary layer, and the mutual transformation process of "balance unbalance balance" promotes the updates and appreciation of knowledge.

5 Conclusions

The flow characteristics of viscous fluid are extended to the analogy analysis of the knowledge management in this paper. Some conclusions can be summarized as follows:

1) The contradictory relationship between knowledge stickiness and knowledge transfer in the knowledge management is illustrated based on the boundary layer theory in fluid mechanics. The boundary layer theory of knowledge field is put forward to analyse the stickiness and fluidity of knowledge, which extends the conception of knowledge field, and enriches the theory of knowledge management.

2) The boundary layer dynamic model of knowledge field based on the features of sticky knowledge transfer is constructed to discuss the dynamic mechanism of sticky knowledge transfer. The knowledge transfer conservation equation according to the law of conservation of knowledge stocks is built to further explore the updates and appreciation of knowledge in the transfer process of knowledge.

3) The thickness of boundary layer for each organization is dynamic. On the one hand, the features of knowledge, such as value, importance, specificity, and complexity, are constantly changing with the variety of time and the development the society, which changes the viscosity of knowledge and the thickness of boundary layer; on the other hand, there are knowledge transfers between inside the boundary layer and outside the boundary layer, knowledge creation and usefulness of knowledge declining in knowledge field, which can also make the thickness of boundary layer transformed.

4) The arguments about the rotation or not of knowledge field are explained through the boundary layer phenomenon of knowledge stickiness. It is believed that knowledge field is rotatable owing to the knowledge stickiness. Due to the fact that the stickiness of knowledge outside boundary layer is small, the rotation of knowledge field outside boundary layer is small and even negligible. However, inside the boundary layer, the rotation of knowledge field is large because of the large stickiness of knowledge. We can also maintain that, the knowledge field inside boundary layer is rotational, and the knowledge field outside boundary layer is irrotational.

Design of real-time clock based on ARM embedded system

Lijuan Liao*

College of Computer Science and Technology, Taiyuan University of Technology, 030024, China

Received 1 March 2014, www.cmnt.lv

Abstract

Real-time clock of ARM processor has disadvantages such as dependence on the processor, low interrupt level and unadjustable accuracy. Linux embedded system based on ARM processor is provided with independent real-time clock using X1227 real-time clock chip. In addition, the work presents transplant of uCLinux system in S3C2440A, procedure of system boot loader and frame of Linux character device driver, thus achieving design of RTC driver based on I2C protocol of uCLinux system.

Keywords: S3C2440A, RTC, X1227

1 Introduction

Real-time system (RTS) is that correct calculation depends on logical validity of procedure and resulting time. If time constraint of system is not satisfied, the system will go wrong. Then real-time clock is applied to RTS. Software counting can be used to realize function of real-time clock by the timer in ARM processor. However, it is not universal because of the disadvantages including data loss after power down, low interrupt level, unadjustable accuracy, etc. Real-time clock, with independent crystal oscillator and power supply system, can constantly run, thus providing reliable time for RTS and avoiding trouble. By using I2C bus, X1227 real-time clock chip has wide supply voltage range, high interrupt level and adjustable accuracy, thus promoting achievement and correct operation of RTS.

2 S3C2440A microprocessor

S3C2440A microprocessor of Samsung Corporation is applied to embedded system using a new bus structure—Advanced Micro controller Bus Architecture (AMBA). The CPU is a 16/32-bit ARM920T RISC processor designed by Advanced RISC Machines (ARM). ARM920T has a cache architecture consisting of MMU, AMBA BUS and Harvard. The architecture has independent 16KB instruction and 16KB data caches comprising eight-byte lines. S3C2440A is provided with a complete set of common system peripherals to reduce cost of the whole system and additional components [1].

The real-time clock integrated in S3C2440A is controlled by INT_RTC and INT_ADC, which have the lowest priority in all the 26 interrupt sources. Besides, this real-time clock is not universal, and cannot run with support of 3.3V voltage and microprocessor. Therefore, external RTC chip X1227 is applied.

3 RTC chip X1227

3.1 INTERNAL STRUCTURE OF X1227

X1227 is a real-time clock with functions of clock/calendar, CPU monitoring circuit and two-way query and alarm. Dual port clock and alarm register can ensure the accuracy of clock work, even during read and write operation. Clock/calendar can be provided with functions of controlling and reading by registers. Clock can precisely display the time by the unit of second, minute, hour, day, week, month and year using a 32.768 kHz crystal with low cost. There is a watchdog timer in X1227. If the watchdog timer overtimes, the reset pin $\overline{RESET}$ will be activated. X1227 has an input pin V_{BACK}, using a non-rechargeable battery as the back-up power. A 4K-bit EEPROM array in X1227, used as configuration data memory, will be safe and not affected when the main and standby power supplies lose efficiency. Figure 1 shows block diagram of X1227 consisting of control registers, SRAM, EEPROM, I2C serial interface decoder, status registers, standard crystal, watchdog timer, etc [2].

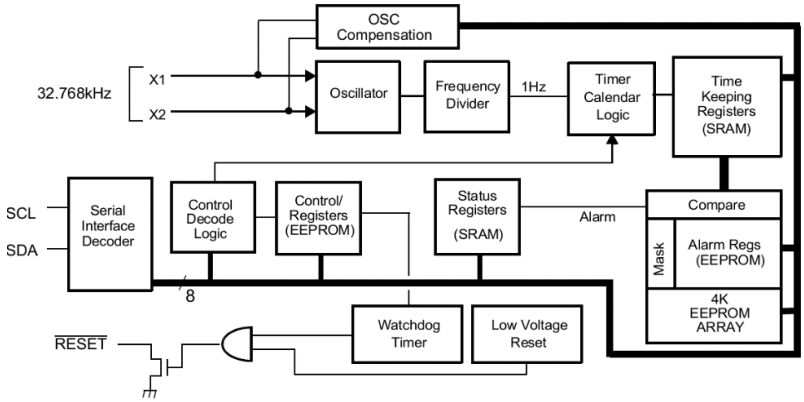

FIGURE 1 Block diagram of X1227

3.2 MAIN FUNCTIONS OF X1227

RTC of X1227 uses a external quartz crystal with a frequency of 32.768 kHz to keep accuracy of year, month, day, week, hour, minute and second. RTC, with century byte, can adjust leap years, the months less than 31 days, and the form of time by one bit. After format conversion, data of CCR in form of BCD code should be read and written by I2C interface in X1227. There are two alarm registers in X1227. If the time set by alarm register is the same with RTC, the corresponding position of SR register in CCR will be set to 1, thus realizing timing alarm. There are four KEEPROMs in X1227. They will be used to store key data of self-check program and system when system is power off. WatchDog can be set to control the shortest time of feeding the dog by writing WD1, WD0 of BL register in CCR. When the procedure comes into endless loop because of external disturbance, and timing register reaches maximum, WatchDog will emit a signal to reset SCM, thus the procedure is in control again.

X1227 is connected with S3C2440A using I2C interface (See Figure 2). Serial data pin (SDA), as a bi-pin connected with external 330Ω pull-up resister, is used to input and output data to the device. Input of serial clock pin (SCL) is used to time the whole data of input and output devices, thus providing serial clock signals of data transmission. VCC and VBACK inputs are received by the power control circuit of X1227. If VCC< VBACK-0.2V, then the power will be switched to VBACK by the power control circuit; if VCC＞VBACK, then it will return to VCC.

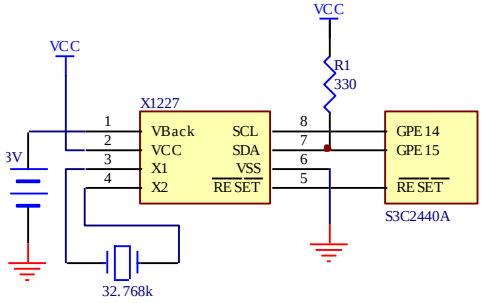

FIGURE 2 X1227 connected with S3C2440A

4 Transplant of uclinux system to S3C2440A

4.1 UCLINUX SYSTEM

Uclinux (micro-control linux), as a Linux system in micro-control field, is a major product of Lineo Corporation and a model for embedded Linux of open source. Aiming at the target processor of embedded system without MMU (Memory Management Unit), uclinux is designed and successfully transplanted to platforms. The users of uclinux operation system can apply the whole Linux API functions based on GNU general license. After clipping and optimization, uclinux forms an embedded Linux with high optimization and compact codes. Uclinux has advantages such as small size, stability, good transplant, excellent network function, perfect support to all the file systems and abundant API functions. Therefore, uclinux has good compatibility with Linux. API functions of uclinux, except fork(), are the same as those of standard Linux [3].

4.2 ESTABLISHMENT OF CROSS-COMPILING ENVIRONMENT

Cross-compiling environment used for target machine is established in PC because of limited storage of common embedded system. The executable files, got from compilation, connection and location of procedure in PC, are loaded to the target machine through serial port. Cross-compiling environment is required to establish kernel header files, binutils, bootstrap gcc, glibc, etc. The work applies the method as follows. Firstly, GCC is installed in PC aiming at compiler of ARM (arm-elf-gcc). Secondly, the configured cross tool chain "arm-elf-tools-20040427.sh" provided in "www.uclinux.org" is convenient to use. In the root directory, after adding the executed authority by running command "#chmod 755 arm-elf-tool-20040427.sh", the script can be operated to install cross tool chain in correct position. At last, the address "/user/local/bin" is checked to identify whether the compiling environment file started with "arm-elf-" is existed or not. If so, then cross-compiling environment

will be successfully installed. The program above is actually procedure of establishing uclinux library file.

5 Driving X1227 in unlinux system

5.1 SYSTEM BOOTSTRAP ROUTINE

BOOT, as the first running line of code in the chip after power on, is applied to initialize running environment of hardware and software in system for application program operation. System bootstrap routine boots up operation system and hands the control power over to operation system core. This operation depends on the type of CPU core and the resource applied to develop embedded system software in CPU chip. Figure 3 shows the flow of system boot loader based on this chip and application program.

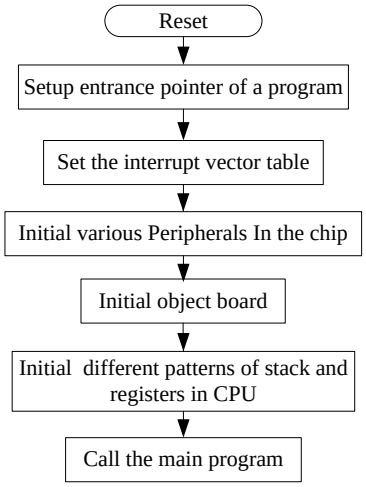

FIGURE 3 Flow of the system boot loader

5.2 DRIVER FRAMEWORK OF LINUX CHARACTER DEVICE

X1227 as well as alarm clock is set and read by compiling software. As a hardware device of system running in Linux, X1227 is operated by drivers in Linux operation system. The devices in Linux include character and block. X1227 is a character device. Programs of user mode can run character devices like common files. Therefore, the driver of character device type should at least realize system call functions including open(), release(), read() and write(). In Linux kernel, X1227 character driver is designed based on the framework as follows [4].

```
struct file_operations {
ssize_t(*read)(struct file *, char *, size_t, loff_t *);
sszie_t(* write)(struct file *, const char *,size_t, loff_t *);
int(* ioct1)(struct inode *, struct file *, unsigned int,Unsigned long);
int(* open)(struct inode *, struct file *);
int(* release)(struct inode *, struct file*);
...};
```

The driver should realize the following functions:

1) open( )

Initialize the devices supported by the driver.

2) release( )

Close the devices supported by the driver after use.

3) read( )

Read data from character devices by application program or Linux.

4) write( )

Write multiple byte data to character devices.

5) ioctl( )

Provide application program with some special operation which cannot be easily realized by read() and write() methods.

The above methods derive the functions as follows: initialization, load and release of hardware devices; management of equipment including setting real-time parameter and providing unified operation interface for devices; reading data of device files obtained from (or responding to) application program; detecting or processing device errors.

5.3 DESIGN OF X1227 DRIVER

X1227 can communicate with ARM by I2C bus. Using signal wires SCL and SDA, I2C bus can achieve data interaction between devices, thus simplifying occupation of hardware resources and PCB wiring space. I2C bus realizes data transmission and command control by timing signals including start, stop and ACK. If SCL is at the high level and SDA switches from high to low level, I2C bus will start sending signals; if SCL is at the high level and SDA switches from low to high level, it will stop sending signals; if the device receives 8-bit data, it will send ACK to the sender. Then the sender will set SDA at the high level, and the receiver will set SDA at the low level during responsive clock pulse, thus achieving signal response. Figure 4 shows start condition, stop condition and ACK of I2C bus [5].

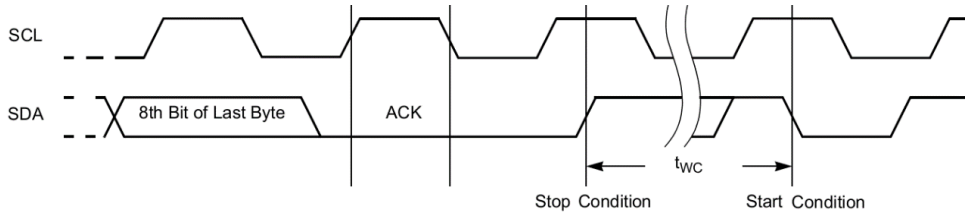

FIGURE 4 I2C bus

X1227 has slave device addresses including 1010 (access to 4KB EEPROM) and 1101 (access to CCR) used to control RTC and WatchDog. Figure 5 shows operation of a byte access including a slave address byte, an address

word (16 bits) to be accessed and an 8-bit operand. The last bit of the slave address byte determines this operation. If the last bit is 1, the reading will be conducted; if 0, writing will be operated. The communication process of I2C bus is simulated using I/O interface. Firstly, slave address of I2C bus is defined to read and write devices by program.

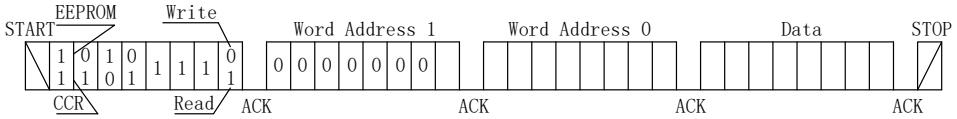

FIGURE5 Access format of X1227

 # define RTC_I2C_READ 0xaf //Read the address by I2C bus
 # define RTC_I2C_WRITE 0xae // Write the address by I2C bus

RTC driver module applies character devices achieved by "struct file_operation" framework structure:

```
static struct file_operations x1227_fops = {
.owner = THIS_MODULE,
.ioctl = x1227_ioctl,
.open = x1227_open,
.release = x1227_release,
};
```

In this structure, the whole functions are accomplished by upper call function ioct1 [6]:

int x1227_ioctl(struct inode *inode, struct file *filp, unsigned int cmd, unsigned long arg)

In the function, reading and writing transmission commands of cmd are "RTC_RD_TIME" and "RTC_SET_TIME"; arg is the structure pointer directing to "struct rtc_time" for time storage. At first, the function reads transmission command cmd to determine whether the operation is writing or reading. If the result is reading, then Function rtc_read() will be called to read data from the register and keep them in arg; else if writing, then Function rtc_write() will write data to the register.

Function rtc_read() can be used to read the time and date in RTC register, achieved by the following function:

```
rtc_r ead (struct file * filep, cha r * buffer, size_t length)
{ ...
Init_Iic( ) ; / / Initialize I2C bus
RdBy _Iic( 0xde, 0x30, & (rdata) ) ; / / Read second register
dbu f[0] = rdata ;
RdBy_Iic(0xd e,0x31 , &(rdata)) ; / / Read minute register
dbuf[1] = rdata;
...
RdBy_Iic(0xd e,0x35,&(rdata)) ; / / Read year register
dbuf[5] = rdata;
copy_to_user (buffer,dbu, f6) ; / / Change data from kernel to user mode
...}
```

Function rtc_write() is mainly used to set time and date.

The compiled program can be re-compiled using cross-compiling tool of uclinux for operation in S3C2440A. In Windows, uclinux kernel, root file system and executed file are read and written through serial port of hyperterminal. Basic settings are as follows: baud rate is 115200; data bit number 8; no parity checking; stop bit 1; no data flow control.

6 Conclusions

RTC is one of the typical applications of I2C in embeded products. Even if there is no special I2C interface to control processor chip, I2C bus time sequence will be simulated by software to achieve communication between chips with two I/O interface pins. Therefore, RTC is suitable for embedded devices. The work aims at designing driver of X1227 clock chip to achieve real-time clock combined with RTC device driver model in uclinux. The design realizes real time of system by replacing the integrated clock in CPU. The designed clock has a good performance in running and function, thus proving practicability and stability of this driver design.

Spatial and temporal mining method using GPS data

Xiaolei Li*

School of Electronic and Information, Ningbo Dahongying University, Ningbo, Zhejiang, 315175, China

Received 1 March 2014, www.cmnt.lv

Abstract

Geographic information has spawned many novel Web applications where global positioning system (GPS) plays important roles in bridging the applications and end users. Learning knowledge from users' raw GPS data can provide rich context information for both geographic and mobile applications. However, so far, raw GPS data are still used directly without much understanding. Spatial-temporal data analysis plays an important role in many applications, including transportation infrastructure, border security and inland security. To analyse the moving patterns of vehicles on a road network, a measure for determining the similarity of vehicle trajectories with respect to space and time has to be defined. Although previous research has addressed the trajectory similarity problem, most of the studies focus on Euclidian distance instead of network distance. This paper deals with the variations in applying a spatial-temporal similarity measure with given Points of Interest (POI) and Time of Interest (TOI), treating spatial similarity as a combination of structural and sequence similarities that is evaluated using the techniques of dynamic programming. The similarity set thus formed will be used by the remote database to broadcast trigger-based messages to participating vehicles in a neighbourhood for future route- and information-sharing activities. The performance of the scheme is evaluated using experiments on standard real-life data.

Keywords: K-means, clustering algorithm, error rate, iteration, reduction, stable

1 Introduction

The increasing pervasiveness of location-acquisition technologies, such as GPS and GSM network, is leading to the large collection of spatial-temporal datasets. Such datasets have supported a variety of novel Web applications, in which locality and mobility usually connect to one another closely. For instance, people can tag user-generated contents like photos with locations; trace their outdoor mobility; and use location-based services. Recently, a branch of GPS-track-sharing applications using Web maps appeared on the Internet. In this category of Web applications, people can record their travel routes using a GPS-equipped device and then share travel experiences among each other by publishing these GPS tracks in a Web community. GPS-track-sharing offer a more fancy and interactive approach than text-based articles to better express people's travel experiences, which provide users with valuable references when planning a travel itinerary.

However, so far, these applications require people either to manually label their own trajectories or to use raw GPS data such as GPS coordinates and timestamps without much understanding. Neither of these methods is optimal to the development of such applications. Actually, users become easily frustrated by the additional data labelling effort, and then give up uploading their data. Moreover, people intend to understand an individual's mobility, and learn information about user behaviours as well as user intentions behind the raw data. Being an important kind of human behaviour, transportation modes, such as walking, driving, and taking a bus, can enrich their mobility with knowledge and provide pervasive computing systems with more contexts.

In recent years, information technology has significantly penetrated surface transportation. The transportation environment is embedded with various mobile sensors, including on-board GPS receivers, sensors mounted on public transportation vehicles and pedestrian cell phones. These sensors continuously generate spatial-temporal data and enable applications such as vehicle tracking and environmental monitoring. Studying people and vehicle movements within a certain road network is both interesting and useful, especially if it can be used to understand, manage and predict the traffic flows. By studying the massive flow of traffic data as a trajectory, the traffic flow can be monitored and traffic-related patterns can be discovered. The development of Intelligent Transportation Systems (ITS) allows better monitoring and traffic control to optimize traffic flow.

Advances in social networking and location-based services are increasingly creating new, sophisticated mechanisms that can foster a seamless integration of information among travellers to provide alternatives and support sustainable economic and social policies. All of these issues raise challenges to the dissemination of information, such as safety, traffic, entertainment, service and content, in a vehicular network. In all of the above cases, a major challenge arises from the fact that the relevance of information changes with time and with the location of the vehicle. The quality of data is measured by their spatial-temporal relevance, which indicates the probability that the resource will still be available when the vehicle reaches it. For example, in the case of the

***Corresponding author** e-mail: xiaoleilizj@yeah.net

dissemination of service information (e.g., the availability of parking spaces), the temporal and spatial delivery of information must be carefully considered. In the moving object database, which will have the complete history of the vehicle's trajectory, a spatial-temporal trajectory similarity search process will identify vehicles with very similar movement patterns with respect to space and time. Based on such a similarity set, useful information can be disseminated among neighbouring vehicles in the same similarity set containing extensive applications (e.g., knowing customer preferences, re-routing and scheduling of further travel, and so on). One advantage of this system is that because the broadcast message came from an official central database, it will be more authentic, and thus the nodes can be confident in the messages they have received. However, when internal nodes share information based on the central broad-cast, the system has to go through a confident management process to ensure the accurate dissemination of information. This paper relates how the spatial-temporal similarity measure of vehicle trajectory will help to better disseminate information in vehicular networks for data mining applications.

In this article, we aim to automatically infer transportation modes, including driving, walking, taking a bus, and riding a bicycle, from raw GPS logs based on supervised learning. It is a step toward recognizing human behaviour and understanding user mobility for pervasive computing systems. Also, it is a step toward improving local/mobile applications on the Web and enhancing the connection between mobility and locality by mining knowledge from raw GPS data with minimal user efforts. The contributions of this work lie in the following three areas.

First, we propose a change point-based segmentation method. This method aims to partition each GPS trajectory into separate segments of different transportation modes, while maintaining a segment of one mode as long as possible. In addition, this segmentation method is capable of enhancing the reliability of our methodology facing the variable traffic conditions.

Second, from each segment, we identify a set of sophisticated features, such as direction change rate, velocity change rate, and stop rate. These features have few correlations with the velocity, hence are not affected by differing traffic conditions. These set of features can also be extended to other pervasive computing systems aiming to recognize human behaviour and understand user mobility.

Third, we conduct a graph-based post processing algorithm to further improve the inference performance. In this algorithm, we mine the common sense constraints of the real world and typical user behaviours on a location from user-generated GPS logs. Therefore, we are able to leverage this location-constrained knowledge as probabilistic cues, while maintaining our methodology being in-dependent of an additional database of road networks or points of interests.

Overall, the advantages of our method over the related works include two parts.

1) Our method is independent of other sensor data like GSM signal and heart rate, and map information, for example, road networks and bus stops, etc. Thus, it is generic to be deployed in a broad range of Web applications.

2) The model learned from the dataset of some users can be applied to infer GPS data from others; that is, it is not a user-specific model.

2 Related Works

In conventional approaches, the location information of a moving vehicle is expressed as a geometric coordinate (x, y) in two-dimensional space. However, Lee et al. (2007) express location information using both the hierarchical administrative district and road network in one-dimensional space, more accurately fitting the real world. For instance, if a moving object is in a building at latitude of 125.58 and longitude of 37.34, then it can be expressed as a set of fields according to an administrative district, such as the city, road name, or block (e.g., Seoul, Main Road, 165th block). The dimension reduction of spatial-temporal data management (Abraham and SojanLal, 2008) discusses two algorithms for binary encoding pro-cess: one for location encoding and one for converting a position represented as geometric coordinate into an equivalent binary string. Because the proposed similarity scheme is based on this encoding method, these basic algorithms are briefly discussed below.

Many recent studies regarding data management in vehicular networks and related topics discuss the VANET, while very few focus on the processing of spatial-temporal information. In the case of traffic and service information, Xu et al. (2004) suggest aging information with time and distance. Information is opportunistically pulled from neighbouring vehicles as a target vehicle moves in a given area. Such information needs to have time and location stamps. Because either the vehicle moves farther away from where the information is relevant or time elapses, the information is aged and eventually purged. This enables vehicles to maintain up-to-date information without taxing memory and other resources. Xu et al. and Wu (2004) discuss the propagation and survival of information in time and space. Because of the spatial-temporal relevance of information, a piece of information tended not to propagate beyond a specific boundary. In time, a given piece of information would propagate very quickly until it reached a maximum number of copies, at which point it would also rapidly decline. Wolfson et al. (2005) discuss the dissemination of resource discovery (e.g., parking spaces) using spatial-temporal information. Each disseminated report represents information about a spatial-temporal event, such as the availability of a parking slot or a cab request. Reports are disseminated by a peer-to-peer broadcast paradigm in which an object periodically broadcasts the reports it carries to encountered objects. The

authors evaluated the value of resource information in terms of how much time is saved when using the information to discover a resource.

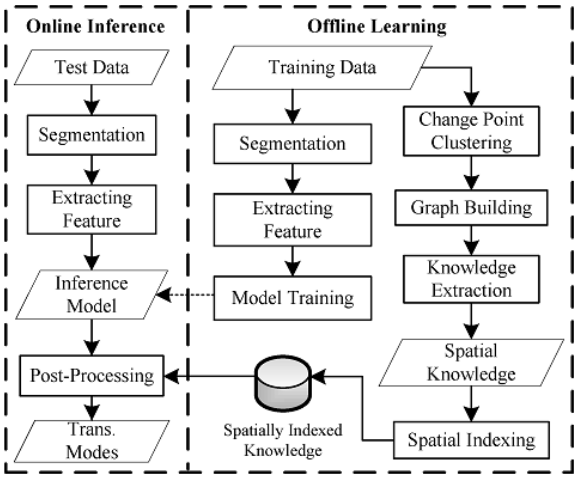

FIGURE 1 Architecture of our approach

The efficiency and reliability of information dissemination will be impacted by how vehicles are clustered when they form and leave groups, how apart they are under different traffic conditions, the density of vehicles and so on. Naumov et al. (2006) simulated realistic vehicular traces, which form trajectories. The authors demonstrated that the realistic traces are noticeably different than those in widely used mobility models. Szczurek et al. (2010) provide another promising approach to the dissemination of spatial-temporal information, such as the current traffic condition of a road segment or the availability of a parking space. Ranking becomes critical in this situation by enabling the most important information to be transmitted under the bandwidth constraint. Delot et al. (2010) proposed a vehicle-to-vehicle communication system for data sharing in vehicular networks using the concept of Encounter Probability to share information. The objective of this paper is to facilitate the dissemination of information between vehicles when they meet each other, taking into account the relevance of the data to the drivers and the type of event (e.g., available parking spaces, obstacles in the road and information relative to the coordination of vehicles in emergency situations) in the network.

Recently, some works (e.g., Delot et al., 2011) have addressed the problem of processing queries in a highly dynamic vehicular network in order to share information between vehicles. Queries interesting in pervasive and mobile computing environments (Vargas-Solar et al., 2010) are usually location-dependent (Ilarri et al., 2010). In vehicular networks, vehicles usually receive data from its neighbours and decides whether they are relevant enough to be stored in a local data cache. Then, a query processor can use the data to retrieve relevant data for the driver. Delot et al. (2011)discuss the challenges and possible solutions of multi-scale query processing techniques to exploit, at the mobile device's level, different access modes (e.g., wireless networks, push, pull) and various data sources (e.g., locally cached data, data stored by vehicles nearby and remote Web services) to provide users with results for their queries. Wolfson and Xu (2010) discuss various research issues related to the methods of routing, navigation, and tracking in transportation networks (the spatial-temporal database) that may involve multiple modes (e.g., train, bus, private car and bicycle).

3 The proposed spatial-temporal mining method

The algorithm for mapping locations in binary code is a recursive procedure, which will successively divide the entire region into sub-regions, map each district into a two-dimensional space and assign a binary string to each district. The total conversion time increases almost linearly with the number of two-dimensional locations, and more than seven million locations can be pro-cessed per second. The characteristics of the binary encoding scheme discussed above, which is used as a baseline in the proposed similarity scheme, are the following: It will be easy to determine the lowest common administrative district by extracting the longest common prefix of a given set of binary strings, and a district containing a set of lower districts can be represented by the range of binary string (i.e., county ''A'' will be represented by the range [00000, 00111]). These advantages make it easy to address the whole country, whole district or a single road by identifying the common prefix in the binary string representing the location of the object. For example, an object's location on the road may be encoded as 001010000110010, where first two bits denote the country, the next four bits denote the district, the following five bits denote the road and the final four bits denote the relative location on the road. Thus, if the first two bits in all of the locations are 00, they all belong to the same country.

3.1 ARCHITECTURE OF OUR APPROACH

As shown in Figure 1, the architecture of our approach includes two parts, offline learning and online inference. In the offline learning section, on one hand, we first partition GPS trajectories into segments based on change points and extract features from each segment. Then, the features and corresponding ground truths are employed to train a classification model for online inference. On the other hand, using a density-based clustering algorithm, we group the change points detected from all users' GPS logs into clusters. Subsequently, a graph based on these clusters and user-generated GPS trajectories is built.

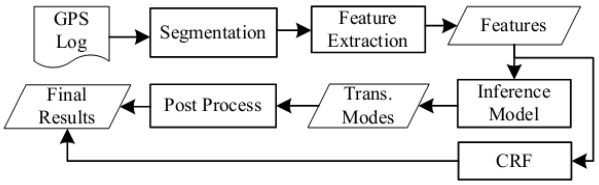

FIGURE 2 Procedure of inferring transportation mode

From this graph we can mine some location-constrained knowledge, such as the probability distribution of different transportation modes on each edge. The knowledge can be employed as probabilistic cues to improve the inference performance in the post processing. In addition, a spatial index is built over the detected spatial knowledge to enhance the processing efficiency. In the online operation, when a GPS trajectory comes, like the offline training process, we first partition it into segments and extract the same features from each segment. Second, given the features, the generative inference model will predict the transportation mode of each segment in a probabilistic manner. Third, given the probabilities of a segment being different transportation modes, a post-processing algorithm is used to improve the inference accuracy by leveraging the spatial knowledge mined from the training data. Finally, the transportation mode with maximum posterior probability will be selected as the ultimate result.

3.2 INFERENCE STRATEGY

As shown in Figure 2, when a GPS Log file comes, first, we divide the GPS track into trips and then partition each trip into segments by change points. Then, we extract the features from each segment and send these features to the inference model. Two alternative ways are considered when we attempt to learn a user's transportation mode. In one way, we regard the segments of GPS tracks as independent instances. General classifiers like Decision Tree are employed to perform inference. After the inference, a post-processing, which takes the transition probability between different transportation modes into account, is implemented to improve the prediction accuracy. In the other way, GPS data are deemed as a kind of sequential data. Conditional random field (CRF) [13], a framework for building probabilistic models to segment and label sequence data, is leveraged to perform the inference. Since the conditional probabilities between different transportation modes have been considered in the CRF graphical model, in this way, we do not take the post-processing. In the inference, the mode of transportation can take four different values including Bike, Bus, Car and Walk. At the same time, we do not discriminate driving private car from taking taxi. Both of them are deemed as Car.

3.3 SPATIAL KNOWLEDGE EXTRACTION

Figure 3 illustrates the four steps toward mining spatial knowledge from users' GPS logs. The knowledge includes a change point-based graph and the probability distribution on each edge of the graph. First, given GPS logs with labeled ground truths, we can get the special points consisting of change points and the start/end points of each GPS trajectory. These special points were subsequently grouped into several nodes (clusters) using a density-based clustering algorithm. The reasons we prefer to use density-based clustering instead of agglomerative methods, such as K-Means, lie in two aspects.

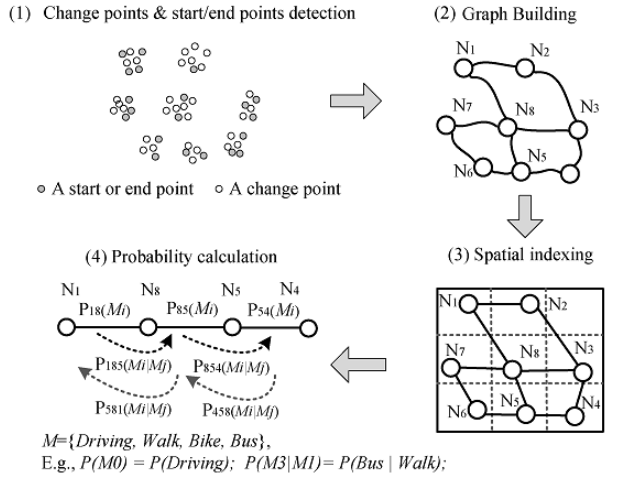

FIGURE 3 Mining spatial knowledge from GPS logs

First, a density-based approach is capable of detecting clusters with irregular structures, which may stand for bus stops or parking places. Second, it can discover popular places where most people change their transportation modes while removing sparse change points representing places with low access frequency.

Second, with the GPS trajectories from multiple users' GPS logs, we can construct an undirected graph. In such a graph, a node represents a cluster of the special points mentioned above, and an edge denotes users' transitions between two nodes. Here, we do not differentiate various trajectories with similar start/end points; that is, all the trajectories passing two graph nodes are regarded as similar trajectories.

Third, we build a grid-based spatial index over the graph to improve the efficiency of accessing the information of each node and each edge. The space covered by the graph is partitioned into many disjoint grids. Then, the graph nodes falling in different grids are associated with the grids. Therefore, when a new GPS trajectory comes to be inferred, we only need to match the special points detected from the trajectory against the graph nodes pertaining to the grids where these special points falling in. Of course, this step is optional unless the scale of the GPS dataset is quite large.

Fourth, we are able to calculate the probability distribution of different transportation modes on each edge. For instance, as depicted in the fourth step of stands for the likelihood of the event that people take buses on the edge between node 1 and node 8. Further, the conditional probability be-tween different transportation modes can also be computed based on the graph, for example, (Bus |Walk) represents the transition probability from Walk to Bus between edge 18 and edge 85. In other words, it denotes the likelihood of the event that a user walks from node 8 to node 5 based on the observed occurrence that the user takes a bus from node 1 to node 8.

Such previously mentioned knowledge is promising in improving the inference accuracy due to the following reasons:

1) This implies people's typical behaviors among different places. The clusters of change points represent the places many people change their transportation modes. Usually, these places could be bus stops, parking lots, and railway stations. We can take into account user behavior among these nodes as probabilistic cues when we infer other trajectories passing these two nodes.

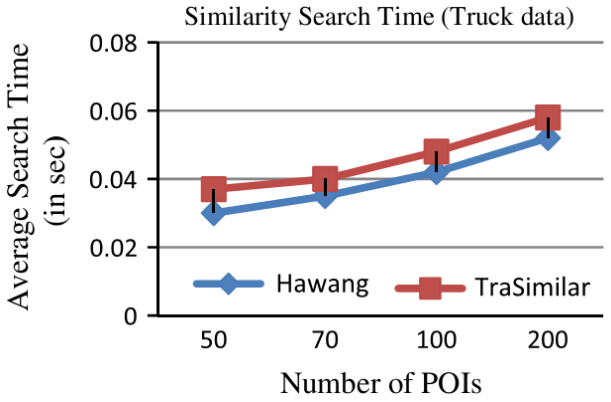

FIGURE 4 Comparison of the average search times for the truck dataset

Naturally, for example, if most users take a bus between two nodes, we can suggest that the two nodes could be bus stops, and the edge between them could have a very high probability of being a bus line.

2) The probability on each edge implies constraints of the real world. For instance, buses only take passengers on at bus stops, cars are left in parking lots, and cars and buses only travel on streets, etc. This knowledge mined from multiple users' GPS logs take advantages of the location constraints while keeping our method independent of an additional map database. In such a way, it is not necessary to match each GPS trajectory against the road network. Mean-while, we do not need to maintain a database of bus stops, railway stations and parking lots.

4 Experimental Results

This experimental setup focuses on vehicle trajectories in which two common characteristics are assumed. First, vehicle trajectories typically follow road networks (i.e., they are not free movements in two-dimensional space). Second, vehicle positions are measured at a reasonably good temporal resolution (e.g., one GPS measurement per minute). Many existing vehicle trajectory datasets satisfy the above resolution requirement, such as the truck data set and the INFATI data derived from the INFATI Project (Jensen http://www.infati.dk/uk). Both of these datasets were used in this research, resulting in one GPS measurement for every 30 s.

In this study's experiments, the performance and scalability of similarity search techniques have been evaluated. All experiments have been conducted on a Intel Core 2 Duo machine running Windows XP with 2 GB of RAM and a 320 GB.

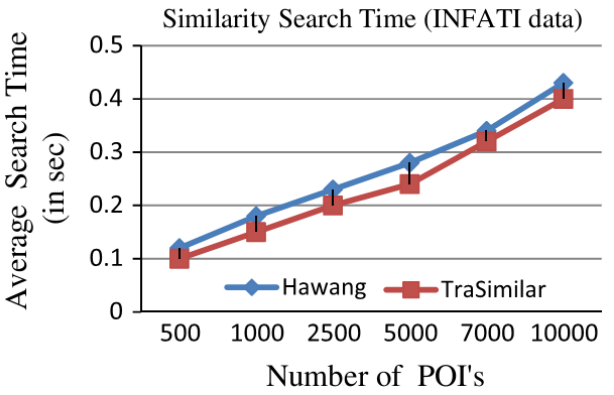

FIGURE 5 Comparison of the average search times for the INFATI dataset

SATA2 16-MB hard drive. The performance of the similarity search technique of the proposed algorithm is measured by comparing the average search time with that of the Hawang algorithm for different numbers of POIs, ranging from 50 to 300 for small datasets (truck data) and from 500 to 3000 for large datasets (INFATI data). Scalability is measured in terms of how the search time grows with respect to an increase in the number of POIs. The truck dataset consists of 50 trucks delivering concrete to several construction places around the Athens metropolitan area in Greece for 33 different days. The data set has 276 trajectories and 112,203 GPS points (approximately one GPS measurement for every 30 s in most trajectories). This study's approach can be used to analyse other vehicle trajectory datasets with similar temporal resolutions, such as the Milan data set. The structure of each record in truck data set is as follows: {obj-id, traj-id, date (dd/mm/yyyy), time (hh:mm:ss), lat, lon, x, y}, where (lat, lon) is in the WGS84 reference system and (x, y) is in the GGRS87 reference system.

As shown in Figure 4, the experimental results confirm that the average search time of the proposed spatial-temporal similarity algorithm increases linearly with an increase in the number of POIs, supporting the fact that the algorithm is scalable. As both of the graphs are similar in terms of average search time, the search performance of TraSimilar is con-firmed to be similar to that of the earlier algorithm even when the proposed spatial similarity extends the structural and sequence similarity measures.

The similarity search performance was tested with a large GPS log dataset (INFATI) of car movements to consider a large number of input trajectories and a POI number greater than 300. The INFATI data are derived from the INFATI Project, which is an intelligent speed-adaptation project carried out by a team of researchers at the Department of Development and Planning, Aalborg University. For each car that delivered data, the INFATI data contains one file with GPS log data.. As shown in Figure 5, the experimental results for a large number of POIs confirm the scalability and search performance of the

algorithm in agreement with the results for a smaller number of POIs. The results of the experiment also shows that the TraSimilar search performance is better than that of the Hawang method when there is a larger number of POIs. The authors claim that this is due to the proposed method's advantage of reduced dimensions when representing location and trajectory data in the binary-encoded scheme.

5 Conclusion

Our approach consists of three parts: a change point based segmentation method, an inference model and a post-processing algorithm based on conditional probability. The similarity set thus formed will be used by the remote database to broadcast trigger-based messages to participating vehicles in a neighbourhood for future route and information-sharing activities. The performance of the scheme is evaluated using experiments on standard real-life data.

In this paper, by using knowledge mined from raw GPS data, we aim to improve geographic applications on the Web and build closer connections between locality and mobility. The knowledge we gained as well as the connections enable more novel applications and improve user experience in a variety of tasks. An approach has been proposed to automatically learn transportation mode from raw GPS data. The inferred transportation mode can help Web users more deeply understand their own experience while better sharing other users' knowledge. It also enables context-aware computing based on a user's present transportation mode and creation of innovative user interface for Web users. The proposed approach is independent of other information and devices. Therefore, it is universal to be performed in both mobile devices and servers.

Abstract

Watershed transform is a key operator in image segmentation algorithms. However, the computation load of watershed transform is too large for real-time applications. Previously published watershed segmentation algorithms required at least three global synchronization points: minima detection, labelling and flooding. This paper presented an algorithm of watershed transformation based on opening-closing operation and distance transform. It improved the classical watershed segmentation algorithm based on distance transform, overcoming over segmentation. The experiment result demonstrated that this method for segmentation inherits the advantage of watershed algorithm based on distance transform that it successfully segment out each dowel in the image bringing convenience to computer vision and auto-counting of dowels. It also overcame over-segmentation existed in traditional watershed segmentation preserving the original edges of each dowel in the image completely. This algorithm can be combined with any image segmentation algorithm to give more precise segmentation results. An example is also shown by combining a background registration and change-detection-based segmentation algorithm with Watershed. This new video segmentation algorithm can give accurate object masks with acceptable computation complexity.

Keywords: watershed transform, image segmentation, automatic segmentation method

1 Introduction

Image segmentation is the process of building a partition of the image into connected regions, such that picture elements (pixels) of the region are homogenous according to some criterion (gray value, motion, etc). In this paper, we will focus on the watershed transform which is a mathematical morphology method for segmenting images. Most of the time, the watershed transform is applied to a gradient image for extracting homogeneous regions with respect to luminance. This gradient image is considered as a topographic relief, and watershed segmentation amounts to extracting significant basins in this relief. Watershed is a fundamental approach in a variety of fields, like image compression, coding, and analysis. It is used in telecommunication, biomedical, physics, satellite picture analysis, fast imaging system, etc. However, watershed segmentation is a computationally intensive task.

Watershed transform, which can separate an image into many homogeneous non overlapped closed regions, has been widely applied in image segmentation algorithms. It is also applied to image sequences as a core operator of video segmentation, which is a key technique in MPEG-4 content-based encoding systems. Video segmentation algorithms with watershed transform are taken as mainstream since they can generate object masks with accurate boundaries.

Many watershed algorithms have been proposed. Vincent and Soille proposed a watershed algorithm using immersion simulations. With sorting before the flooding process and with priority queue, this algorithm is dramatically faster than any former ones. Beucher and Meyer's algorithm also uses immersion simulations. Two types of algorithms are included: one creates watershed pixels and the other produces a complete tessellation of an image. An ordered queue is used in this algorithm, whose concept is similar to that of Vincent and Soille's algorithm; however, the minima of the input image need to be detected and labeled first, thus increases the complexity of this algorithm. Dobrin et al. proposed a fast watershed algorithm named split-and-merge algorithm. It can solve the isolated area problems of the former two algorithms when they are employed to create watershed pixels. Although the results obtained are more correct, it is more complex than the other two algorithms. Moreover, watershed transform for video segmentation is often required to produce a tessellation of an image, where the isolated area problem would not occur. Moga et al. proposed a watershed algorithm suitable for parallel implementation. With parallel computation, the watershed algorithm can be further accelerated. However, it is also complex and requires a powerful platform, which is impractical for general cases.

Several implementations of the watershed algorithm can be found in the literature: Sequential algorithms by immersion and other algorithms based on topographical distance, like the Hill-Climbing algorithm. Efficient implementations and parallelization of these algorithms have to cope with the problem of non-minimum plateau, which can be solved by using hierarchical FIFO (First-In-First-Out) queues, or by a lower completion of the input image. A recent implementation of a Hill-Climbing

***Corresponding author** e-mail: wwh801225@163.com

algorithm using FIFO queues is presented. The paper surveys approaches for a parallel implementation of the watershed algorithm: most of them are based on the Hill-Climbing algorithm, distributing the image in blocks over the set of processors implemented on a Parsystec supercluster 128 or a Cray3D. The lack of scalability, of these implementations is mainly due to the need for a global synchronization between processors for local minima detection, non-minimum plateau flooding, or lower completion. A fine grain parallelization was also proposed, using an associative net model, although the minimum detection is a prerequisite.

This paper proposes an improved watershed algorithm for image segmentation on the basis that watersheds are highly related to original frame data. It updates watersheds instead of recalculating watershed transform frame by frame. The watershed process can be accelerated, and the results are almost the same as those of conventional watershed algorithms. Furthermore, the segmentation results can be further improved with the intra-inter watershed scheme. In this paper, the watershed algorithm is programmed as a set of concurrent communicating iterative programs that are efficiently mapped onto an asynchronous parallel architecture. This idea was previously suggested and has also more recently been studied with the paradigm of Asynchronous Cellular Automata (ACA), i.e., a lattice of finite state machine interconnected to its nearest neighbours. The general specification of the watershed algorithm we propose is mapped onto an asynchronous processors array which enables us to derive a set of architectures, ranging from a fine grain processing (one finite state machine per pixel), to coarser implementations (a complex finite state machine or program which is able to process several pixels). In the case of fine granularity, this ACA leads to an implementation similar to the associative mesh.

2 Related works

The watershed segmentation technique has been widely used in medical image segmentation. Examples include the work presented in [1, 2], which make use of the watershed transform to segment grey and white matter from magnetic resonance (MR) images. The algorithm originated from mathematical morphology that deals with the topographic representation of an image [3, 4]. The set of pixels with the lowest regional elevation corresponds to the regional minimum. The minima of an image are the groups of connected pixels with their grey level strictly lower than their local neighbouring pixels. The rainfall simulation [3] describes that when rain falls onto the surface, any rain drop reaching a point in the surface will flow along its steepest descent until it reaches a minimum. The paths of pixels, which converge towards a common minimum, constitute a catchment basin. Watersheds are the elevated areas that divide the different catchment basins. The partitions, which we aim to obtain, are the catchment basins, and the boundaries between the partitions are the watersheds. Advantages of the watershed transform include the fact that it is a fast, simple and intuitive method. More importantly, it is able to produce a complete division of the image in separated regions even if the contrast is poor, thus there is no need to carry out any post-processing work, such as contour joining. Its drawbacks will include over-segmentation and sensitivity to noise [2]. There has also been an increasing interest in applying soft segmentation algorithms, where a pixel may be classified partially into multiple classes, for MR images segmentation [5-7]. The fuzzy C-means clustering algorithm (FCM) is a soft-segmentation method that has been used extensively for segmentation of MR images [8]. However, its main disadvantages include its computational complexity and the fact that the performance degrades significantly with increased noise. K-means clustering algorithm [9, 10], on the other hand, is a simple clustering method with low computational complexity as compared to FCM. The clusters produced by K-means clustering do not overlap.

In past few decades, various segmentation techniques have been pro-posed. Generally, they are based upon two basic properties: similarity and discontinuity. Pixel similarity gives rise to region-based segmentation [7-9], whereas pixel discontinuity gives rise to edge-based segmentation [10-12]. These two traditional techniques may be able to get good result for some simple images. However, it is always difficult to achieve desired result for HSRI segmentation due to the complexities of the landscape structure on the image. While textures in objects, such as forest, are always detected as spurious object boundaries, which cause over-segmentation; the edges between the farm fields may appear to be obscure that may induce under-segmentation. With regard to these problems, many works have been done. Some researchers integrated texture in segmentation to avoid the over segmentation of spectral heterogeneous objects [13]. In this strategy, the texture calculation before segmentation is time-consuming. Moreover, the texture boundary effect [14] may induce the location uncertainty of the extracted object boundaries. Some researchers proposed to segment image at multistage, then select and merge the optimal scale of segmentations to achieve good result [15]. However, how to select the optimal scale for different type of ground objects and merge them is still a difficult task that needs further research. Some researchers tried to integrate edge information into segmentation to get more accurate object boundaries [16]. This strategy takes the advantage of both region-based and edge-based segmentation techniques and is more practical for the quick and effective processing of large size data.

3 The proposed method

3.1 BASIC IDEA OF THE PROPOSED METHOD

Watershed algorithm is usually applied to the gradient image. Imagine the gradient image is a topographic surface,

a hole is drilled in each minimum of the surface, and water is flooded into different catchment basins from the holes. As a result, the water starts filling all catchment basins, which have minima under the water level. If two catchment basins would merge as a result of further immersion, a dam is built all the way to the highest surface altitude and the dam represents the watershed lines. This flooding process will eventually reach a stage when only the top of the dam is visible above the water line. The result is a tessellation of the input image into its different catchment basins, each one characterized by a unique label.

The method is a two-stage process, including the extraction of marker image and the labelling of pixels (flooding). Markers are a set of components marking flat regions of an image, i.e., each marker indicates the presence of an object. If the object interiors (markers) are set to 1, and the uncertainty areas are set to 0, we get a binary marker image. It contains a set of components (markers) marking the core regions and a large number of pixels may remain unassigned. The next step is then to label the unassigned pixels by the extended watershed algorithm dealing with markers to get the final partition. It has the advantage that segmented results can have coherent regions, link edges, no gaps due to missing edge pixels. However, applying this method to HSRI segmentation, the noises or textures on the image are usually labelled as the pseudo-local minimum regions and result in over-segmentation. To reduce over-segmentation, we make some improvements to the marked-based watershed segmentation algorithm. First, a regional adaptive marker extraction method is proposed. The marker image is created from gradient image by binary processing. Instead of using a fixed threshold, such as H-minima algorithm, a threshold image, on which the threshold of each pixel is statistically estimated and used for binarization. Because it considers the complex grey level distribution of HSRI, the extracted makers are more coincide with the real objects. Then, the image labelling scheme in the Meyer's algorithm is implemented by using one queue and one stack data structure. This scheme can largely save memory cost and make it applicable to large image. The overall framework is shown in Figure 1.

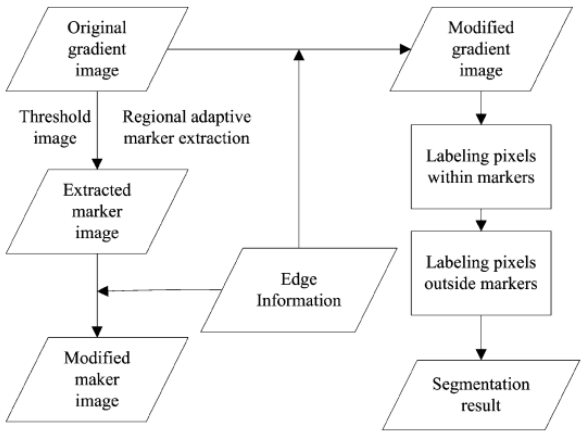

FIGURE 1 Framework of segmentation

3.2 HYBRID SCHEME

Although the segmentation results are almost the same as those of the conventional watershed algorithms, the proposed algorithm may introduce error in the following conditions. First, change detection is not sensitive enough. Second, the minimum of a catchment basin is included in UA, and a part the catchment basin is not included. Third, the scenes change a lot. The error will propagate in the proposed predictive watershed algorithm. The error propagation can be interrupted by inserting a frame where watersheds are generated with the conventional algorithm. These watersheds do not need information from the previous frame, so we have the term "intra watershed" (I-Water-shed). The I-Watershed and P-Watershed hybrid scheme, called IP-Watershed, is illustrated in Figure 2.

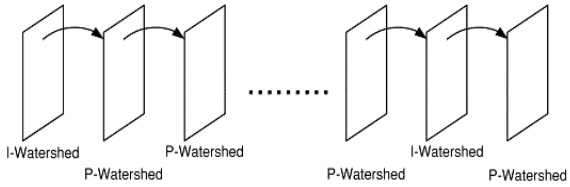

FIGURE 2 I-Watershed frames are inserted to avoid error propagation of Watershed

It can accelerate the watershed process and maintain accuracy at the same time. The time to insert an I-Watershed can be decided with the following two strategies to interrupt the error propagation. To deal with the first and the second error conditions described above, we can insert an I-Watershed frame after a fixed number of P-Watershed frames. The fixed interval to insert an I-Watershed frame depends on the threshold and the error rate required for the applications. After is decided, the error accumulation behaviour, which is the amount of increasing error for each frame, is also decided. An I-Watershed should be inserted when the accumulated error exceeds the required error rate. The less the error accumulated in each frame, the longer the interval to insert an I-Watershed frame; the tighter the error requirement, the shorter the interval. On the other hand, to deal with the third condition, scene change condition, the error rate is monitored in each frame. An I-Watershed frame is inserted dynamically when the monitored error rate exceeds a required value. These two strategies can be employed simultaneously to interrupt error propagation effectively.

3.3 LABELLING PIXELS

The labelling of pixels is the process of assigning each pixel a unique identity (ID). There are two often-used pixel labelling methods.

1) The first method uses the individual markers as the local minima in the gradient image. It filters out the undesired minima of the gradient image, and applies the traditional watershed segmentation on the revised gradient image.

2) The second method suppresses unwanted minima during labelling process. The marker based immersion type watershed algorithm proposed in literature, performs the flooding process directly on the original gradient image. It was realized by using the data structure of hierarchical circular queues. The hierarchical circular queues are a set of queues with different priorities, each queue is a first-in first-out data structure. The priority of each pixel in the gradient image is defined as the reciprocal of its gradient value. This implies that a high (low) priority is assigned to a pixel with low (high) grey-level value. To save memory cost for large image segmentation, we proposed to use a data structure of only one queue and one stack to store the temporary data in image labelling. It can largely reduce the memory cost. The pixels are first sorted in a descending order of priority. Then the possible neighbour labelled pixel of each unlabelled pixel is searched by seed tracing to identify the label ID for the current processing pixel. In the search process, one queue (QU) and one stack (ST) are used. In labelling pixels, the pixels within marker and the pixels outside makers are labeled successively.

During labelling the pixels outside the markers, the pixels labeled lastly are more possible to be on the watershed line. To make sure that the edges are labelled as the object boundaries, the gradient image is rectified by assigning the largest gradient magnitude value to the edge pixels first. The unlabelled pixels are processed in a priority value descending order. ST and QU are used to store the unlabelled pixels. For each priority level, there are two steps. In the first step, only pixels with priority higher than the current processing priority are pro-cessed. These pixels can be divided into two groups. The first group includes pixels with higher priority but not labelled in the previous labelling process, and they are stored in QU. The second includes all the unlabelled pixels with priority. The first group of pixels are processed in advance to the second one. After the first step, if the pixel cannot be labelled, it is stored in ST and processed in an reverse order in the second step. If after the second step, the pixel still cannot be labelled, it will be stored in QU and processed together with the pixels of which the priority is lower than marker-based watershed segmentation result. The labelling operation on pixels outside the markers is dependent upon the number of IDs labelled to the neighbouring pixels of the seed pixel. As same as the process of labelling the pixels within the markers, if two pixels are in the same region, their common neigh-boring pixels should not be edge pixels at the same time. This rule should be obeyed in the counting of the number of the ID; the same ID is counted only once, moreover the neighbouring pixel is not counted if it breaks the rule.

3.4 WATERSHED SEGMENTATION

In order to improve the computing speed of segmentation, in this paper a new algorithm is used. The new algorithm is called defined intuitive watershed algorithm that based on the "immersion" watershed algorithm proposed by Vincent and Soille.

The two algorithms have the same process, including sorting and flooding. To be specific, in the same gradient level, Vincent-Soille algorithm uses a FIFO queue to expand gradually from the inside out of the catchment basin. The new algorithm is to scan each pixel according to spatial relationship (from top left to bottom right), and to determine each pixel to belong to an existing catchment basin or a new one. The fundamental basis of the judgment is whether the pixel has marked adjacent pixels. If it has, it belongs to the catchment basin of its marked adjacent pixels. Otherwise it is to be a new minimum region and assigned a new regional marker. In order to avoid the generation of error minimum regions, two concepts of "error catchment basin" and "combined array" are introduced. Specific steps of segmentation are as follows:

1) Sorting: the new algorithm in the calculation of the sorting position takes the spatial location of pixels into account, so the elements of the sorted array meet a certain spatial relationship. The form of values of sorted array is: (X coordinates, Y coordinates, the gradient value).In this array, the smaller the gradient value is, the more forward the position will be. If the gradient value is the same, the pixel in the upper left (of spatial position) is in front.

2) Flooding: for each current scanned pixels, check its 4 adjacent pixels (or 8 adjacent pixels).if one of the 349 adjacent has not yet been marked, then turn to the next adjacent. If the entire adjacent are not marked, a new catchment basin is found and given a new marker. If one of the adjacent has been marked and the current pixel is not yet, then assign the marker of the adjacent to the current. If one of the adjacent and the current are marked, it may find an error minimum region or a watershed ridge lines.

3.5 WATERSHED CONTAINERS

According to implementation of the watershed segmentation algorithm, water is made from the process of spreading each storage pelvic gradually, namely the marked regional internal gradually to the edge of the area adhesions recursive. If the regional in image containers is too finely, which the whole image will be partitioned an infinite number of adhesion areas, if each containers correspond corn grain, it can guarantee the smooth implement impoundment process in grain internal. Therefore build excellent containers and water-shed, will directly determine the adhesion of particle swarm segmentation quality and efficiency. Through the edge detection has won the ideal watershed border, it should also ensure that the pelvic area between each grain to separate and divide boundary adhesion, and with low value area for the entire area.

1) Implementation taking binary processing after purification grayscale image in adaptive threshold;

2) Adapting radius of 10 pixels by type of structure elements, disk, operating binary image corrosion;

3) Taking negative after marking corrosion image, while assure background region pixels for "0" still, corrosion area of pixels is negative;

4) It will take the normalized image edge detection and buy negative corrosion images obtained by, and take "0" as a background, based on the negative marker value for storage, with "1" at the image matrix for watershed.

Through the above treatment, which ensure each corn grain image to have separate water, and relatively clear watershed, pelvic value is negative marker value, fantastic value close to "1", other areas are "0". The recursive operation process that from high value low value area regional was labelled by image of each grain, which like pixel gradient are uniformity, does not exist small containers and omit the impoundment of the interference of computation quantity and containers. It could improve the reliability and efficiency of operation, what's more, because each grain is a relatively independent starting point (saucers). Even though the public boundary (adjacent grain watershed) is discontinuous (existing gap), it also can ensure the effective segmentation adhesion areas. But if grain region and background area are linked, water that rising to a certain height from pelvic will inflow the background. Now water district have not reached threshold. It will mistake the background region as part of the grain area. The original image background region is "0" (black), via the single grain area, only after influenced by impoundment computing, in central small area isn't effected by leak influence, other areas are marked the not "0" value (white). According to the type of (1) method to implement the marker images, taking purification processing to leaked background, it can take "0" background region, the marker value of each grain regional remain unchanged.

4 Experimental results

Block size analysis for determining the optimal block size is shown in Figure 3.

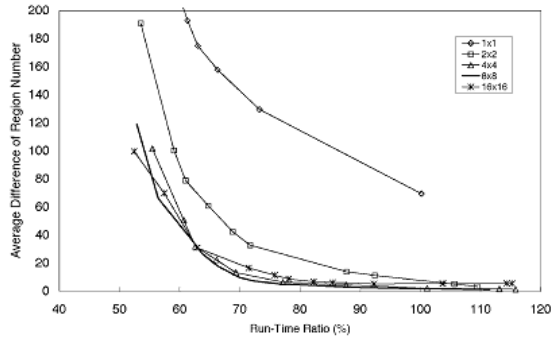

FIGURE 3 Block size analysis showing that 8X8 is the optimal block size.

The accuracy of the segmentation results is evaluated by the difference in region number, that is, the less average difference in region number between the results of the conventional algorithm and the proposed one, the higher the accuracy. Since regions in UAand outside UAare both processed with the conventional watershed algorithm, the positions of watersheds must be very close to those of the conventional algorithm, and only the over-segment problem may occur. The region number information is enough to evaluate the accuracy of watersheds, i.e., the closer the region number is between the result of the conventional watershed transform and that of the proposed one, the more accurate the proposed algorithm is. The ratio of the run time of the proposed algorithm to that of the conventional watershed algorithm is used as another criterion in this analysis. For each block size, a different threshold value is tested to decide the runtime-accuracy curve shown in Figure 3. The lower the threshold, the higher the runtime ratio, and the lower the average difference of region number. The test sequence is Children. Figure 3 shows that 8X8 is the optimal block size because it can provide higher accuracy with less run time than other choices. Several sequences were tested to give a similar conclusion.

The region number corresponding to a different run time is shown in Figure 4.

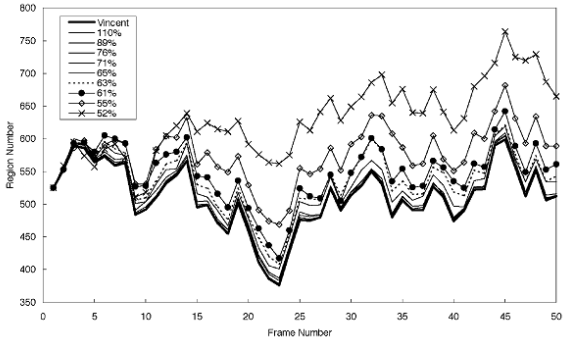

FIGURE 4 Region number of different run-time situations

As can be seen, when the run time increases, the similarity between the results of the conventional watershed and the proposed one also increases. When the run time is reduced to 61%, the region number is still very similar to the reference results. The execution time compared with Vincent and Soille's algorithm. Only core operations of watershed are recorded, namely, the gradient operation, sorting process, and flooding process. Note that the average difference in region number is fixed at 5% in these experiments. The simulation results show that the proposed algorithm can save 20%–50% of the computation. Moreover, the results of the conventional and proposed algorithms are similar. Consequently, the proposed algorithm can reduce computational intensity while maintaining segmentation quality.

5 Conclusions

Aiming at the limitation of watershed segmentation, this paper presents an algorithm of watershed transformation based on opening-closing operation and distance transform. It improves the classical watershed segmentation algorithm based on distance transform, overcoming over-segmentation. The experiment result demonstrates that this

method for segmentation inherits the advantage of watershed algorithm based on distance transform that it successfully segment out each dowel in the image bringing convenience to computer vision and auto-counting of dowels. It also overcome over-segmentation existed in traditional watershed segmentation preserving the original edges of each dowel in the image completely.

A new predictive watershed algorithm named Watershed for video segmentation is proposed in this paper. Taking into consideration the temporal coherence property of the video signal, the watershed algorithm can be accelerated. It updates watersheds in changing parts while keeping watersheds in other parts of a frame. The watershed process can be accelerated, and the results are almost the same as those of the conventional watershed algorithms. Moreover, the segmentation results can be further improved with the intra-inter watershed scheme. The proposed algorithm can be combined with any video segmentation algorithm to improve the segmentation results.

Abstract

How to improve the text categorization efficiency as well as keeping high speed is a research problem. Several factors are effected the processing of the decision tree construction, such as, the degree, the balancing degree, the constructing way, the group number and the division degree between groups etc. Considered the various roles between the above factors, a comprehensive algorithm to construct the SVM-DT (Support Vector Machine - Decision Tree) is proposed. In this method, three conditions are considered respectively. The text categorization experiments on massive corpus demonstrate that the algorithm can improve the efficiency in some degree and decrease the training and testing time largely at the same time. The algorithm to construct the SVM-DT is feasible and adaptable.

Keywords: Text Categorization; Support Vector Machine; Decision Tree; Multi-class category; Corpus; Positive Sequence Tree

1 Introduction

By constructing the best classified hyperplane, the Support Vector Machine (SVM, [1]) can rightly classify the samples, which is proved to be one of the most powerful text categorization methods. However, the SVM was originally developed for binary decision problems. If SVM is used to deal with multi-class classifier with the massive data, the calculating overhead is too huge. The popular methods for applying SVMs to multi-class classification problems usually decompose the multi-class problems into several two–class problems that can be addressed directly using several SVMs. The typical methods are the OAO (One-Against-One) method [2], OAA (One-Against-All) method [3], DAG-SVM (Directed Acyclic Graph-Support Vector Machine) method [4] and SVM-DT (Support Vector Machine-Decision Tree) method etc. Among them, DAG-SVM can solve the problem of "Rejecting Recognition" existing in OAO and OAA, but its generalization ability is limited. SVM-DT takes advantage of both the efficient computation of the decision tree architecture and the high classification accuracy of SVM, which is suitable to large categories [5].

There are many researches to constructing SVM-DT. Based on the information gain of the non-leaf node, Ramaswamy [6] proposed a method to construct a tree called Partial Sequence Tree; in this structure each SVM classifier separates one class from the remainders. The advantage of the method is that the classes at the top level of the tree had very high accuracy (more than 95% sometimes), but the ones at the lower levels (especially the last leaf node) had poor accuracy.

Madjarov etc. [7] applied ensemble learning techniques to constructed a tree structure called Positive Sequence Tree, in which each SVM classifier divides the classes into two groups. By contrast, the classifier with positive sequence tree was faster than the one with the partial sequence tree; and the accuracy between the classifiers on the different levels was relatively stable.

Takahashi and Abe [8] proposed four types of decision trees including the above two trees. But the reparability measure of the Euclidean distance or the Mahalanobis distance could not reveal the features of the texts because it only used the number of the words. And it did not explain which type was better under certain conditions. From these papers we can find that the type of the tree is an important effect to the category.

A balanced decision tree which included the tradeoffs between the sample number and the difficulties to divide was employed in [9]. Although it could decease training time in large degree while did not reduce the recognition rate, and it exaggerated the category effect of the "super class".

According to the massive text sets, in this paper we aim to find the effecting factors of SVM-DT construction and how to integrate many strategies while balancing the category precision and the working speed. The remaining parts of this paper are organized as follows. In Section 2, we introduce the strategies to construct the SVM-DT. Section 3 presents our algorithm and text categorization system based on the Section 2. Section 4 describes our experiments respectively done on English and Chinese corpus. Conclusions and further discussions are given in Section5.

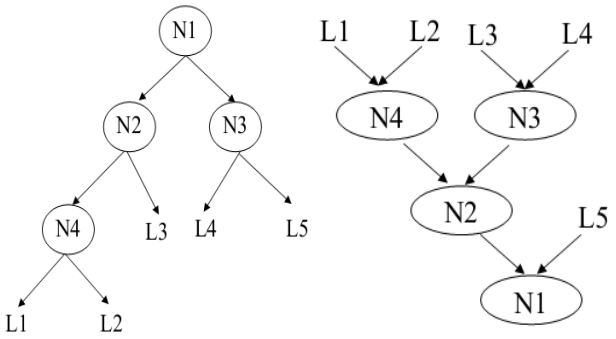
2 Constructing strategies of SVM-DT

In this section, we describe the constructing strategies of the SVM-DT, that is, the depth, the balance degree, the constructing way, the group number and the division degree between groups. These are the most important problems to consider when constructing the SVM-DT.

2.1 SVM-DT CONSTRUCTING MODE

According the constructing direction, the SVM-DT constructing way can be divided into: top-bottom division method and bottom-top accumulation method [10]. The former(Shown as FIGURE 1(a)) begins from the root and grows down to the leaves, which finds two classes which have the minimum distance and then divides the nodes. The similar dividing process will be done until each node points to one class. The latter(Shown as FIGURE 1(b)) first finds two nearest classes from all the samples and combines them into one new group, then recursively continues the finding and combining process until the last two groups are combined into one group.



(a) top-bottom mode (b) bottom-up mode

FIGURE 1 Constructing diagrams of SVM-DT

Both the division method and the accumulating method have $O(n^2)$ (n is the group number of the current notes) time complexity when finding two nearest groups. The calculating consuming is too large for multi-class category when the number of the texts is very big. So, one improving direction is how to reduce the unnecessary calculations.

2.2 EFFECT OF THE SAMPLES SCALE

The scale of the training and the testing sets tends to vary largely. To Reuters corpus, for example, the largest group is composed of 2,877 training documents, at the same time, there are 75 groups of the training documents are less than 10 articles. So when constructing a decision tree it is not appropriate to treat each group equally. Another example is on news sites, the category about the "business and economy" or "entertainment" will contain more pages than that about the "health and medicine" or "education" categories. Therefore, if the larger sets can be broken down earlier, the pressure to the latter work will be greatly reduced.

2.3 CONSTRUCTING STYLE OF DECISION TREE

We have known there are two kinds of constructing way for a decision tree [11]: (1) the Partial Sequence Tree, the two sub nodes of a non-leaf node describe the relation of one-vs.-many (1: n). (2) the Positive Sequence Tree, the relation of the child nodes of a parent node is many-vs.-many (m:n). It has been proved that during the categorization process the partial sequence tree having the bigger depth is slower than the positive sequence tree having smaller depth and higher paralleling degree. So when construct the tree we will try to build a positive sequence tree.

2.4 SIMILARITY BETWEEN THE CLASSES

If the classification performance is not good at the upper node of the decision tree, the overall classification performance becomes worse. So we should put the classes with bigger differences or higher classifying accuracy on the upper nodes of the decision tree, in order that the lower ones may be less affected. To realize that, we can calculate the similarity, then firstly place the groups with less similarity on the upper level.

Based on the above four problems, we present a hybrid strategies to construct SVM-DT: (1) the up-down dividing method is perfect; (2) large set in the samples should be divided out firstly to reduce the calculating overload; (3) the number of sets is tried to be balanced as far as possible to reduce the depth of the decision tree; (4) the dividing ability of the upper nodes should be made stronger as far as possible to reduce the accumulating errors.

3 A hybrid constructing algorithm of SVM-DT and text categorization system

In this section, we will introduce a kind of hybrid constructing algorithm of SVM-DT. The text categorization system based on the corresponding SVM-DT is to be provided then.

The symbols used in the following part are shown in Table 1.

TABLE 1 Notations used in the paper

Sym.	Description
S	the samples
K	the number of the set, $K \in [1,\infty)$
S_i	one sample set, $i \in [1,K]$
$Num(x)$	the number of the texts in set x
N_{dg}	the node on the dg ($dg \in [0,\infty)$) level of a decision tree
∂	the scale effecting factor, $\partial \in (0,1)$
β	the similarity effecting factor, $\beta \in (0,1)$s
SB	the buffer of the total processing set
S_A , S_B	the group centred as A or B
$Sim(A,B)$	the similarity of set A and set B
$IG(N)$	the Information Gain value of node N

3.1 THE HYBRID CONSTRUCTING ALGORITHM OF SVM-DT

In our algorithm, three conditions are considered when building the decision tree:

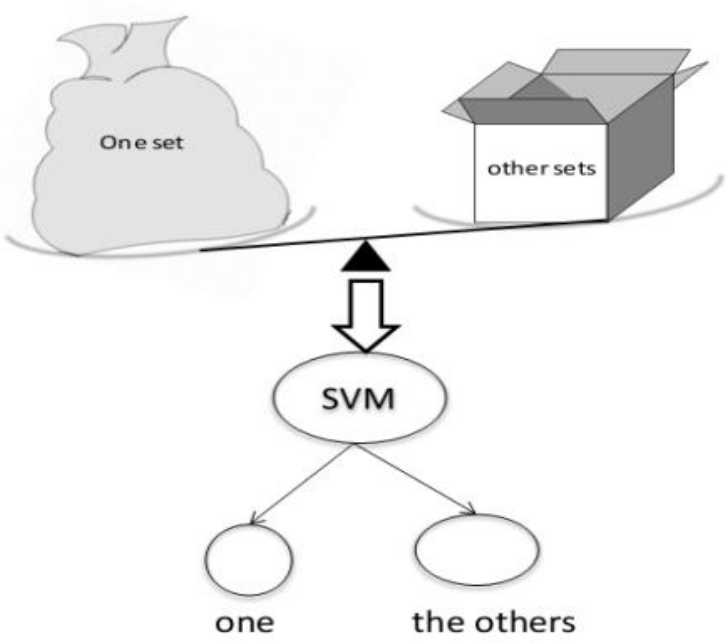


FIGURE 1 The description and the measure of condition (1)

If there is a very large class in the sample sets, we can recognize it only by the number of texts in the set. When the number of texts reaches a certain percentage (∂ here) of the total texts, the set will be put on the upper level first. The parameter ∂ is a value according to the sampling set, usually is set as 1/2 or 1/3 and so on. In our experiment we set it 1/3.

(2) The second condition is that one branch is not too far to divide from the other, which is described as Figure 3.

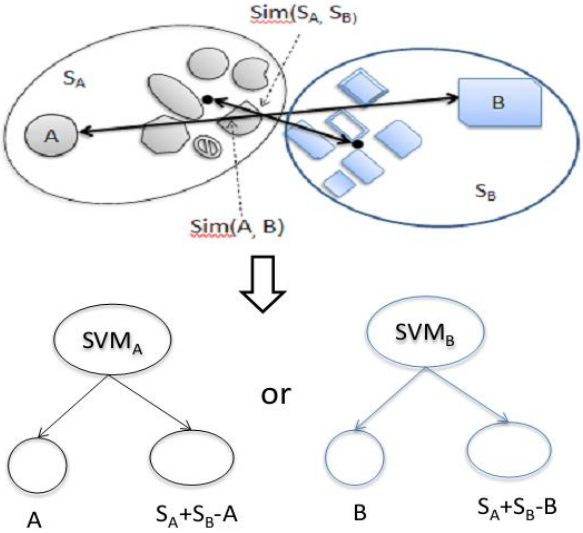

FIGURE 3 The description and the measure of condition (2)

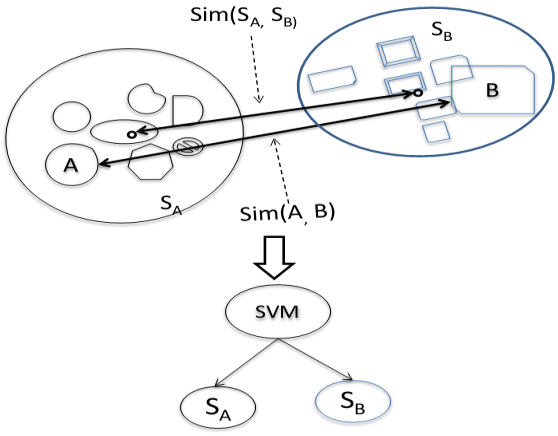

FIGURE 2 The description and the measure of condition (3)

If the gap between the similarity of two groups (S_A, S_B) and the similarity of the two farthest set (A, B) reaches a certain degree, we think A or B is not close enough to the centre of the group. The measure we take is to separate one of them out according to the Information Gain value of the parent node.

(3) The third condition is that two groups are far away enough, shown as FIGURE 4.

This condition should be the most common in the samples. The centre of the group (S_A , S_B) is close to the

dividing node (A , B). So we think two groups can be divided apart. Then a tree structure can be built on S_A and S_B.

The hybrid constructing algorithm for SVM-DT is shown on Algorithm 1.

Algorithm 1 The hybrid constructing algorithm for SVM-DT

Input: training set $S=\{S_1,S_2,...,S_K\}$

Output: a decision tree structure with the corresponding SVM classifiers

// initialization.

$SB=S$; $M=\sum_{i=1}^{K} Num(S_i)$; $dg=0$;

construct a root node N_{dg}.

Step1. let P is the biggest set of SB;

if $Num(P)/M>\partial$ then

{// process the super class P.

construct the sub tree of N_{dg} with the branches of P and $SB-P$;

build a SVM classifier between P and $SB-P$;

$dg++$; $M=M-Num(P)$; $SB=SB-P$;

turn to Step1; // make the sub tree of SB until there is only one set in SB;

}

else {turn to Step2;}.

Step2. //to divide the set into to groups

for each set pair C and D ($C,D\in SB, C\neq D$)

{calculate the similarity $Sim(C,D)$ using formula (3);}

let A and B are the sets which have the lest similarity among those pairs;

for each set P ($P\in SB-A-B$) {

if $Sim(P,A)>Sim(P,B)$

{put P into the set S_A;}

else {put P into the set S_B;} }

if $Sim(S_A,S_B)/Sim(A,B)\leq\beta$

{//to process the class with higher dividing degree

calculate $IG(N_{dg})_A$ with the branches A and $SA+SB-A$;

calculate $IG(N_{dg})_B$ with the branches B and $SA+SB-B$;

if $IG(N_{dg})_A<IG(N_{dg})_B$

{construct the sub tree of N_{dg} with the branches A and $SB-A$;

build a SVM classifier between A and $SB-A$;

$dg++$; $SB=SB-A$; $M=M-L_A$; $N_{dg}=N_{SB-A}$;}

else

{construct the sub tree of N_{dg} with the branches B and $SB-B$;

build a SVM classifier between B and $SB-B$;

$dg++$; $SB=SB-B$; $M=M-L_B$; $N_{dg}=N_{SB-B}$;}

}

else {turn to Step3;}

Step3. //build sub tree of two sets

let S_A and S_B as two branches of the node N_{dg}, construct the tree structure;

build a SVM classifier between S_A and S_B;

$SB=S_A$; turn to Step1;

//make the sub tree of SB until it can not be divided then.

$SB=S_B$; turn to Step1;

//make the sub tree of SB until it can not be divided then;

There are two main factors indicating the algorithm: the huge amount and the distributing character of the texts. So the hybrid algorithm gives an improvement on two sides: (1) the super class can be divided out at the early stage, which aims to speed the construction of the decision tree and reduce much similarity calculation; (2) the balance of two sub trees is taken into consideration, which aims to improve the degree of parallelism and reduce the attraction of the large groups in some degree.

3.2 TEXT CATEGORIZING SYSTEM BASED ON SVM-DT

The text categorizing system (FIGURE 5) is composed of two parts, training part and classifying part, which is connected with the core classifier.

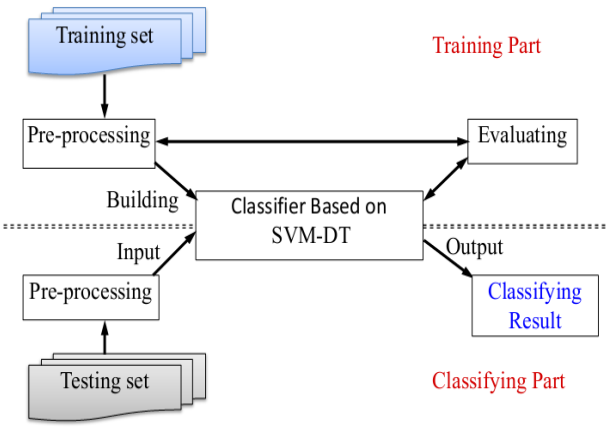

FIGURE 3 Function chart of the text categorizing system based on SVM-DT

Both the training texts and the testing texts should be pre-processed first, which includes the stemming for English texts, word segmentation and tagging for Chinese

texts, stop words removing, feature (words are the features in this paper) selection etc.

The selected feature is weighted by TF-IDF method. $W_{t,d}$ is the weight of word t in text d:

$$W_{t,d} = \frac{TF_{t,d} \times \ln(N / DF_t)}{\sqrt{\sum_{t=1}^{m} [TF_{t,d} \times \ln(N / DF_t)]^2}}. \quad (1)$$

With, $TF_{t,d}$ is the number of t appearing in d. DF_t is the number of the texts including t. N is the total number of the texts.

The text d can be described as a vector V composed of m feature and its weight:

$$V_d = \{(T_1, W_{1,d})(T_2, W_{2,d})...(T_m, W_{m,d})\}. \quad (2)$$

Then, the similarity between vector V_A and vector V_B is calculated as:

$$\mathrm{Sim}(V_A, V_B) = \frac{\sum_{t=1}^{m} (W_{t,A} \times W_{t,B})}{\sqrt{\sum W_{i,A}^2} \sqrt{\sum W_{j,B}^2}}. \quad (1)$$

with, m is the feature both in V_A and V_B.

The aim of the training part is building the classifier based on SVM-DT according to the algorithm 1. Because the classifying result is affected by the feature selection, so we should select the features repeatedly according to the evaluating result.

In training part, each text inputted into the SVM-DT classifier will be divided into one branch of the root node on the basis of the similarities. If the corresponding node is not the leaf node, then we will calculate the similarity and allocate the text to a node recursively until it point to a leaf node. Then the category of the last node is the one that the text to be classified into.

The similarity of two sets can be calculated between the category centres or according to the maximum /minimum distance, the reparability measure matrix. However, the complexity to calculate the reparability measure matrix of two sets is relatively high. Or, much valuable information will be cast away when calculating the similarity with the maximum /minimum distance. So we calculate the reparability between two sets according to the centre vectors similarity of two categories. Let the category L_i contains K texts, C_i is the centre vector: $C_i = \frac{1}{K}\sum_{k=1}^{K} V_k$. Sim_{ij} is the similarity between two categories L_i and L_j, $Sim_{ij} = \left\| C_i - C_j \right\|_2$.

4 Experiment and analysis

In this paper, our experiment system is built on the LIBSVM [12], which is an open source software. The kernel function is RBF. The running environment is 2.66GHz CPU clock speed, 2.0GB memory. We select two types of texts to do our experiments.

English data we used here is from the Reuters21578, which is an open corpus accepted in the field of text category. The total number of the classes is 80. To ensure there is at least one text both in training set and in the testing set, we select 8230 training test and 3200 testing texts. The words in the TITLE and BODY are composed of the texts. After the processes of stemming and stop word removal we get about 20,000 feature words.

To test the application ability of the text categorization system based on the SVM-DT, we collected about 10,000 texts from several famous Chinese news websites such as ifeng, netease, sohu, chnqiang et. al.. The time span of the dataset is a week. There are 36 topics classified by manual works.

4.1 METHOD COMPARISON

To compare with other method, we test three kinds of classifiers.

-- M1: method in Ref. [6] to construct a partial sequence tree.

-- M2: method of Ref. [7] to construct a positive sequence tree.

-- h-M: our method to construct a hybrid type of tree.

Ref.[13] used 8237 texts for testing purpose and 3186 texts to the SVM-DT, which was similar with our texts. The data shown in Ref [13] is our baseline. The precision is used to measure the classified result, calculated as formula (5).

The result of the experiment is shown in Table 2.

TABLE 2 Categorical result of the English texts

Methods	Training Time(s)	Testing Time(s)	Precision(%)
Ref[13]	67	27	94.3
M1	71	36	89.8
M2	62	19	93.7
h-M	56	23	95.9

Comparing with M1 and M2, we could infer that it is quicker to build a positive sequence tree (M2) than a partial one (M1), and the testing time of the former tree is less either. Our hybrid structure (h-M) is the fastest during training period mainly because of the early division of the super class, which avoid a series of the similarity calculation. What's more, testing based on M2 is faster than on h-M, which is reflected by the depth of the tree. Most important, the precision of our method is the best in all the methods. Comprehensively view, our implementation can perform well with relatively quick speed.

4.2 APPLICATIONS

To test the applying ability of the text categorization system based on SVM-DT, we make experiment on the self-built dataset then. The testing texts are randomly held out 1/3 of the total texts and the remaining texts are used to train the system. After 10-fold cross validation, we get the evaluating result. The evaluation index we used here is the standard Precision (P), Recall(R) and F1-measure (F1).

The result based on M1, M2, and h-M is shown on Figure 6.

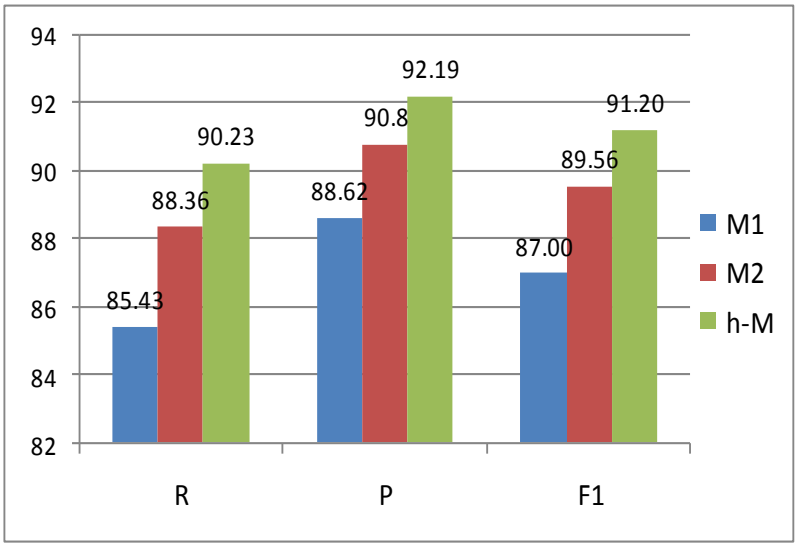

FIGURE 4 Text Categorization result of Chinese texts

On Figure 6, the highest columns are the best results. It is clear that h-M method have got the best values in all the evaluation data. So, we are sure that the text categorization system based on h-M method can distinguish the topics perfectly. Although the time consuming is not the least, the overall performance can meet the demands of the practical application.

5 Conclusion and future work

To SVM, there are two difficulties. One is the lower training speed; the other is the lower precision to deal with the big data. According to the problem, we do improvement on two sides. (1) We notice a hypothesis that the super sampling classes have big differentiation. So, when constructing the tree, we give priority to divide the super class, which can shorten the training time. (2) We make choice to build the branches depending on the disparity of the centre distance between two classes. Our experiment showed that the improvement is effective to reduce the training time, to compress the depth of the tree, to improve the precision comprehensively. Our attempt to balance the classification speed and the efficiency is efficient, which can achieve more feasible method.

Due to the lack of the compared corpus, we did not do the experiment on an open shared Chinese dataset. But our experiment has shown that the hybrid method is not confined to a kind of language. In the future, we can extend our method to the multilingual data. The ability to process the mass data needs to be verified too.

Design of data acquisition node based on CAN bus

Xuewen Yu*

Shunde Polytenchnic, Shunde, Guangdong Province, 528300, China

Received 1 March 2014, www.cmnt.lv

Abstract

Taking single chip microcomputer (SCM) STC90C58AD as control core, a universal CAN bus data acquisition node was designed using CAN bus controller SJA1000 and CAN bus transceiver PAC82C251. Also, the hardware circuit and software design of CAN bus communication were given. Before data collection, current signal has been I-V transformed, and voltage signal has been filtering processed and amplified. Such program is suitable for multi-sensor field data collection in industry.

Keywords: CAN bus, SJA1000, data acquisition

1 Introduction

CAN (Controller Area Network) is the only field bus with international standard at present. Compared to normal communication bus, the CAN bus possesses excellent characters of reliability, real-time and flexibility. As CAN is a multi-master bus, the communication media can adopt twisted pair line, coaxial cable or optical fiber, whose communication rate can reach 1Mbps, and distance can be 10km. CAN protocol adopts encoding the communication data instead of coding the traditional address. Due to its powerful error-correcting capability and support for the transceiver of difference signal, CAN bus has farther transmission distance in highly disturbed environment [1]. This work presents a design of data acquisition node based on the CAN bus. Such node can output the data collected by sensor in the form of digital quantity, which can easily connect to the PC via CAN network, thus simplifying systemic structure and improving accuracy. Meanwhile, several multiple data acquisition nodes can be mounted on CAN bus, realizing the network of data acquisition node. This design is suitable for the data acquisition system whose sensors are dispersed.

2 Topology of CAN bus

Figure 1 shows the topology of CAN bus. System mainly consists of host computer (PC) and data collector. Bus transmission medium adopts the shielded twisted-pair. As the core of the whole system, PC's function is to monitor and manage the system. The function of CAN bus intelligent adapter is to collect the data from each node transferred to PC, and transmit PC's orders to each node. With the multiple host structure of CAN, each node can send data to the bus according to requirements. Because of this, while being monitored by PC, each node can also monitor the bus, thus receiving useful data. Data acquisition node is composed of microprocessors and programmable CAN controller chip, and its function is field data collection and transmission.

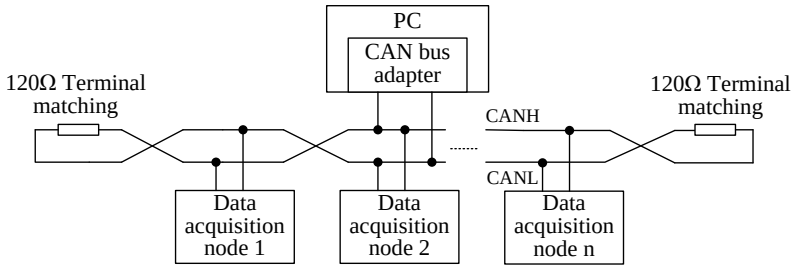

FIGURE 1 CAN bus topology

3 Hardware design of data acquisition node

The main function of data acquisition node includes: Changing the continuous analog signals into digital signals; converting the digital signals into information which is accord with CAN bus protocol; publishing the information on CAN bus. Figure 2 shows the structure diagram of data acquisition node. As shown, the information detected by sensor is sent to programmable amplifier consisted of instrument amplifier AD623 and digital potentiometer X9214. By changing the resistance of X9214, the amplification of signal can be regulated. After amplification, the information will be converted into digital signal by integrated 10-bit A/D converter inside

***Corresponding author** e-mail: xuewenyu_sd@163.com

SCM STC90C58AD. Then, the digital signal will be sent to the bus controller SJA1000. Finally, though photoelectric coupling based on CAN bus protocol, the information transferred from bus transceiver to CAN bus will be received by other nodes and PC.

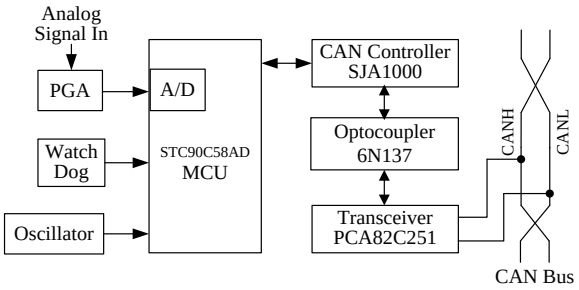

FIGURE 2 Overall block diagram of data acquisition node

3.1 SCM STC90C58AD

Figure 2 shows SCM STC90C58AD, the core processor of data acquisition node. As a new generation introduced by STC, SCM STC90C58ADSTC has the advantages of super anti-interference, high-speed and low-power. Such SCM can work under harsh industrial environments with the features of high speed data acquisition and long working hours. Besides, its instruction code is compatible with traditional 8051 SCM, with the frequency range of 0~40MHz. This SCM has the function of EEPROM for a 40K application space and integrated 256+4096 byte RAM. Moreover, this SCM also supports ISP and IAP for its inner couplers of Watchdog, eight-channel 10-bit A/D converter and three 16-bit timer/counters. In a word, such SCM includes all the unit modules required during data acquisition and controlling. So this SCM is a system with high reliability but low cost.

3.2 DESIGN OF I/V CONVERTING CIRCUIT

The standard current signal outputted by sensor is 4~20mA. To perform A/D conversion and achieve good conversion effects and accuracy, field current signal should firstly be converted into standard voltage 0~5V. It cannot eliminate common mode interference by using circuit network to directly change current signal into voltage signal, and the conversion accuracy cannot be guaranteed. Using the precision current-loop receiver chip RCV420 produced by U.S. company BURR-BROWN, this design can transfer the input signal 4~20mA into 0~5V output signal by current-loop technology. Figure 3 shows the converting circuit with second-order low-pass filter. Both the positive and negative electrodes of RCV420 should connect to a 1μF decoupling capacitor. Besides, two electrodes should be placed close to the amplifier. To avoid the gain and CMR errors introduced by external circuits, the electrodes should connect to ground as the method shown in Figure 3, thus ensuring the minimum grounding resistance. The unused Ref IN pins should be grounded to maintain a high CMRR.

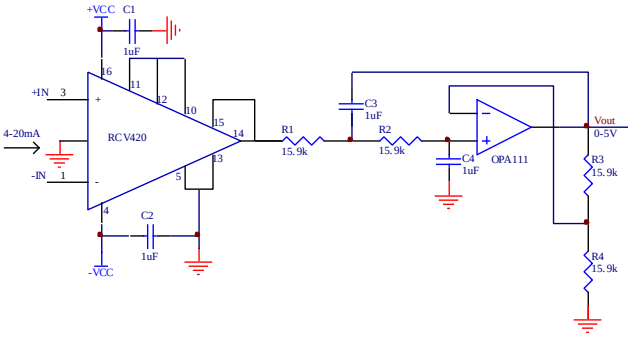

FIGURE 3 I/V converting circuit

3.3 PROGRAMMABLE GAIN AMPLIFIER CIRCUIT

Normal analog voltage signal transformed from industrial sensors includes: 0~5V, 0~10V, ±5V and ±10V. It is impossible for A/D transfer to match all the conditions. If single gain amplification is used, the range of A/D conversion chip cannot be maximized. Furthermore, the measured signal may be saturated, resulting in large measurement error or even damages to A/D chip. Therefore, the gain of preamplifier should be changed according to the output of sensor to obtain the maximum measuring accuracy. This design used the programmable gain amplifier consisted of instrument amplifier AD623 and digital potentiometer X9214. Figure 4 shows the schematic diagram of programmable control amplifier circuit.

AD623 has the advantages of high-accuracy, low-drift and low-noise. And this amplifier can change signal gain by only adjusting the resistance R_G between pin 1 and 8. Moreover, AD623 is easy to be used. The signal gain equation is as follows [4]:

$$G = \frac{49.4k\Omega}{R_G} + 1$$

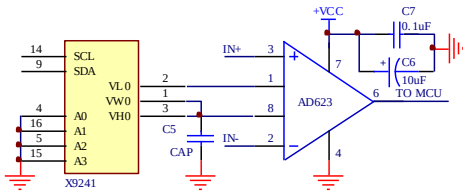

FIGURE 4 Programmable control amplifier circuit

Digital potentiometer X9214 has I2C interface. As shown in Figure 4, VL0 refers to the low end of potentiometer, VH0 the high end and VW0 the movable point. The resistance value of potentiometer between pin VL0 and VW0 can be changed through programming [5]. In specific use, SCM determines the signal range based on the signal value first collected. Then the highest magnification measurement accuracy will be obtained by certain algorithms. Finally, controlling the digital potentiometer X9241 by I2C bus, then the programmable amplification can be reached.

3.4 A/D CONVERTING CIRCUIT

Analog signal, after regulation, will be converted to digital signal by integrated 8-channel 10-bit A/D inside SCM STC90C58AD. The A/D converter interface of SCM STC90C58AD, whose speed can reach 250 KHz, lies in P1 interface. And the converter is a kind of successive approximations ADC. Users can set any one of the eight ways into A/D conversion through software, while the others continue acting as I/O interface. After conversion, the converter should be set at the A/D ending flag bit ADC_FLAG of control register ADC for program inquiring or interrupt application.

3.5 CAN CONTROLLING SJA1000

SJA1000 is an independent CAN controller, supporting the CAN2.0B protocol which has many new features. And the controller lies between the micro controller and transceiver. The CAN core module of SJA1000 is responsible for receiving and transmitting information frame of CAN, as well as realizing CAN protocol. Interface management logic manipulates the interface of the main controller outside. So the operation of STC90C58AD to SJA1000 is equal to that external RAM does [6]. After acceptance filter completes filtering the received information, the information frame that have passed acceptance filtering and without error will be sent to the receive FIFO buffers. Through read-write operation for built-in register of SJA1000, the master controller SCM can be set to CAN bus communication mode, thus achieving data transmitting and receiving. Then, the communication of SCM to CAN controller can be achieved by interrupt mode, which connects interrupt signal pin /INT of SJA1000 to the external pin /INT0 of STC90C58AD.

3.6 CAN TRANSCEIVER PCA82C251

The encoding and decoding of data transmission have been logically achieved by SJA1000. While to connect physical line, the driving capability of differential transmit and receive of CAN bus should be enhanced by means of bus transceiver PCA82C251. Such transceiver can transmit data between two differential voltage bus cables with a high speed of 1Mb/s. Both the CANH and CANL pins of transceiver can connect CAN bus by a thermistor, so as to protect itself from the impact of over-current when resistance heating value becomes larger. Between CANH and CANL, there parallel two small capacitors, which can filter the high frequency interference on bus, and shield electromagnetic radiation. As shown in Figure 5, TX0 and RX0 of SJA1000 are connected to PCA82C251 via high-speed optical coupler 6N137. It is to enhance the anti-jamming capability of CAN bus node and prevent crosstalk between lines. 6N137 is compatible with TTL and CMOS level, with a signal width of 10MHz. So it fully meets the requirement of a communication speed of 1Mb/s for CAN bus signals.

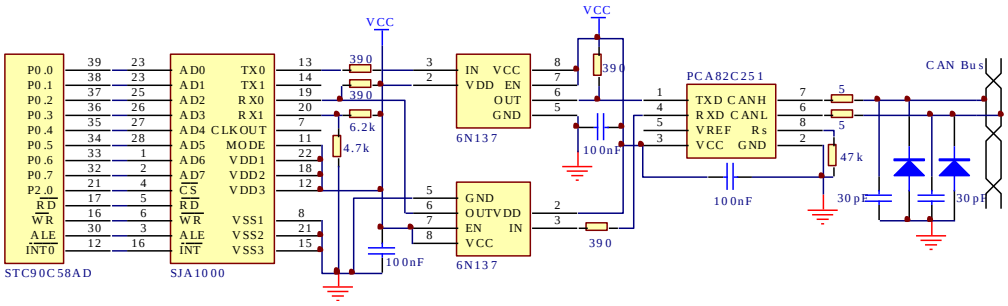

FIGURE 5 Schematic circuit of CAN communication node

4 Communication software design of CAN bus

Communication software design of CAN bus mainly includes SJA1000 initialization, CAN transmitting and receiving programs. Besides, there are some auxiliary functions, like interrupt processing, information processing, bus sleep and awaking treatment, bus error handling and overloading treatment. The modular and structured program design of software design enable the software has good portability.

4.1 FLOW CHART OF MAIN PROGRAM

Figure 6 shows the overall flow chart of software design for system node. When system powered up, part of the reset work would be first completed. Entering the initialization stage, the software would complete the initialization of the rest modules. Following that, system enters the wait state. When received the order of data acquisition from PC, note begins to collect the measured physical signal. Firstly, the analog signal received from the front end of sensor, after be amplified and filtered, should be sent to A/D converter inside SCM for analog/digital conversion. After completion of the signal conversion, results will be temporarily stored in RAM. Then, the data should be processed into CAN data frame until the SJA1000 CAN controller receives the command of data transmission. When PC requires data transmission, interrupt subroutine will start up to transmit data frame. Once transmission finished, system will jump out subroutine. If the data frames on bus need being received, system will receive it. And there is not confliction between

transmission and reception, namely the two processes can work simultaneously. While receiving the command of finishing data acquisition from PC, node will return to the wait state.

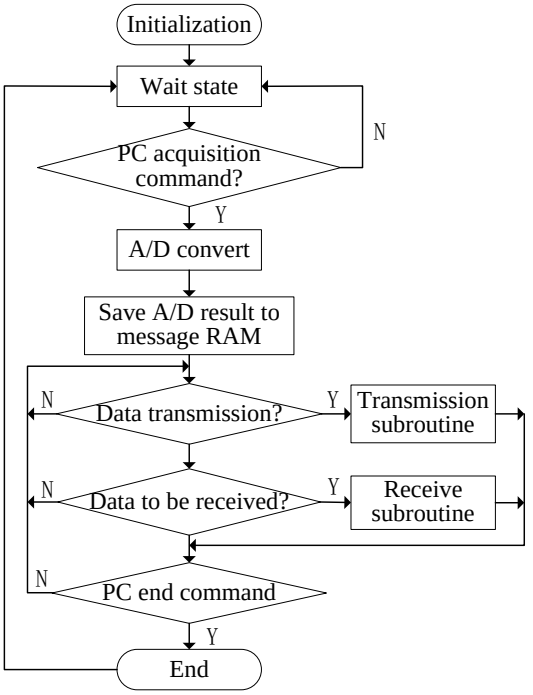

FIGURE 6 Flow chart of the main program

4.2 INITIALIZING PROGRAM OF SJA1000

When using the CAN controller, operator should allocate related registers according to the tasks, namely setting their initialization parameters. However, the initialization of SJA1000 performs only in reset mode. The initialization procedures of SJA1000 mainly includes: selecting work mode, setting interrupt system, setting the bite rate of bus, setting acceptance filter, and setting the output mode and configuration of CAN bus output pins. Actually, these settings refer to the write operations for some registers inside SJA1000. When initialization was completed, the reset request of SJA1000 should be removed. Then, SJA1000 can transmit and receive messages.

4.3 MESSAGE TRANSMISSION PROGRAM OF CAN

Message transmission, namely transforming the information into frame message with required formats, can be automatically accomplished by SJA1000 CAN based on bus protocol. While transmitting CAN message, SCM should first check the state of SJA1000 register. If the state register satisfies transmitting conditions, the data inside SCM will be sent to the transmission buffer of SJA1000. Then, the "transmission request bit" on register will be started by write command. SJA1000 can automatically set the "transmission completion bit" to 0, which means under transmitting. As long as there is another node on bus, such node will transmit acknowledgment (ACK) signal to the bus. If the ACK signal was received by bus, then the node will set to "status bit of transmission completed", which means transmitting successfully. If SJA1000 didn't receive the ACK signal, which means there is no other node on bus. Then SJA1000 will retransmit, and the error register will add one. Before each transmission, it is necessary to read the corresponding bit of state register. And the next frame data can only be loaded when transmission buffer is free. Figure 7 shows the transmission flow of CAN bus.

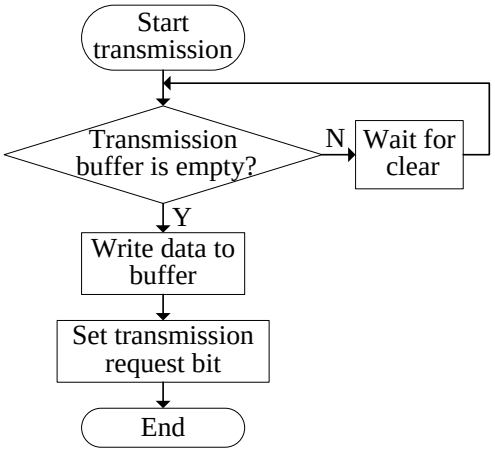

FIGURE 7 CAN bus transmission sequence

4.4 MESSAGE RECEIVE PROGRAM OF CAN

Receive subroutine is mainly responsible for reading the value of receive buffer and dealing with it. For message receive, both inquiry mode and interrupt mode can be used. This work adopts the interrupt mode, which is better than inquiry mode in terms of real-time. When the CAN bus controller SJA1000 receives a valid frame message (have passed filtering acceptance), the pin $\overline{INT}$ of SJA1000 will jump to low level, and the external interrupt 0 of microprocessor will be triggered. If the message was transmitted to microprocessor via interrupt subroutine, then the receive buffer would be released. Figure 8 shows the interrupt receive program sequence of SJA1000.

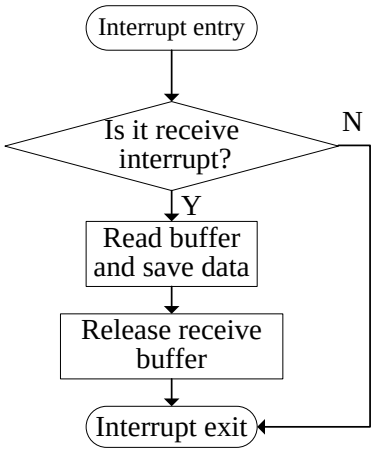

FIGURE 8 Interrupt receive program sequence of SJA1000

5 Conclusions

Due to the use of CAN bus, the system has the advantages of low-cost, small-capacity, multi-channel, high-precision, easy updating, high flexibility and strong extension ability. Analog signal acquisition front is compatible with the old industrial sensors. Therefore, it can well complete the acquisition of field information, as well as simple data processing and communication, with the features of noise immunity and low error rate. The system consists of such nodes can be used as the distributed control system, with complex working environment, various sensors and high real-time requirement.

Reducer optimization design based on chaotic particle swarm optimization (CPSO)

Jiong Cai*

Panzhihua University, Panzhihua, Sichuan, 617000, China

Received 1 March 2014, www.cmnt.lv

Abstract

For the optimization design of two-stage gear reducer, an optimization mathematical model is built in this work to determine the objective functions and constraints. And chaotic particle swarm optimization (CPSO) is utilized to optimize these functions and constraints. Algorithm simulation is carried out based on CSPO algorithm steps, and the results are compared with particle swarm optimization (PSO). Simulation indicates that CSPO can optimize the results of PSO and achieve faster convergence rate.

Keywords: chaos particle swarm algorithm, optimization design, mathematical model, reducer

1 Introduction

As a conventional mechanical device, reducer is widely utilized in heavy machinery including mining machinery, construction machinery and transportation machinery. Its main role is to reduce motor speed or increase motor torque, so reducer optimization design has considerable theoretical and practical value.

2 Particle swarm algorithm

2.1 ALGORITHM PRINCIPLE

Particle swarm [4-7] optimization algorithm simulates predatory behavior of birds, make groups to achieve purpose through the collective cooperation among birds. In particle swarm optimization (PSO) algorithm, a bird is called "particle"; solving group is equivalently bird fauna; the migration from one location to another is equivalently evolution of the population; "good news" is equivalently the local optimization of population; food sources is equivalently the global optimal solution of population. In particle swarm model, the search space is D-dimension; and the total number of particles is n. Each optimization goal is the state of "particles" in the search space, including speed and position. Secondly every particle has a fitness value decided by the optimization function, and also a speed determines their flight direction and location. According to flying experience of oneself and the companions, the particles adjust dynamically the status, that is to say, update oneself through updating two positions. One is the individual best position id p found by particles themselves; another is the global best position found by entire population.

Particle swarm algorithm in operation process randomly generates an initial population and gives each particle a random speed, then update the particle speed and position according to

$$v_{id} = wv_{id} + c_1 r_1 \left(p_{id} - x_{id} \right) + c_2 r_2 \left(p_{gd} - x_{id} \right), \quad (1)$$

$$x_{id} = x_{id} + v_{id}, \quad (2)$$

$$v_{id}\left(t+1\right) = v_{id}\left(t\right) + c_1 rand_1 \left(p_{pid} - x_{id}\left(t\right)\right) + c_2 rand_2 \left(p_{gd} - x_{id}\left(t\right)\right). \quad (3)$$

Randomly generate the initial position and velocity of particle swarm, and then execute iteration according to Equations (1-3) until satisfactory solution was found. Convergence rate of particle swarm algorithm is fast; it is easy to implement and the number of the parameter needed to adjust is less. It has become a new hotspot of study in intelligent optimization evolutionary computation field. Its advantages aroused the attention of academic circles, such as simple implementation, high accuracy, fast convergence rate, strong approximation ability, and the algorithm shows its advantages in the solving actual problem.

3 Chaos particle swarm optimization

For the problem of local optimum in particle swarm algorithm, the work presents the chaos theory for improvement of PSO algorithm, and the process is as follows [8-10]:

1) In chaos initialization, supposing the variable to be optimized is D-dimensional, a D-dimensional vector $z_1 = \left[z_{11}, z_{12}, ..., z_{1D} \right]$ is randomly generated, and each component is within the range of $[0,1]$. Then *M* components are obtained according to the logistic equation [8], $z_1, z_2, ..., z_M$.

$$z_{n+1} = \mu z_n (1 - z_n), n = 0,1,2,...; 0 < z_n < 1; \mu \in [0,4]. \quad (4)$$

***Corresponding author** e-mail: jiongcaipzh@163.com

The chaotic interval will be mapped to the range of variable according to Equation (5).

$$x_{ij} = a_j + (b_j - a_j)z_{ij}, \tag{5}$$

where b_j, a_j are the upper and lower limits of optimized variable, respectively.

2) The fitness value of each particle is calculated using objective function. The *N* particle swarms with better performance are chosen as the initial solution from the *M* initial swarms, randomly generating particle velocity.

3) The initial individual and global extreme of particles are set: the current position of each particle is defined as individual extreme P_i, thereby calculating the corresponding fitness value of each individual extreme based on objective function; the position of particle with the optimal value is defined as global optimum P_g.

4) The flight speed and position of particles are updated according to velocity-position updating formula.

5) Chaos optimization is conducted on optimal position P_g: firstly, the optimal position is mapped to the defined domain of logistic equation [11] using Equation (6). Then, according to logistic equation, the iteration process generates *m* chaotic variable sequences. Finally, these sequences are mapped to the value interval of optimization variable, obtaining *m* particles. Fitness values of each particle are calculated for the optimal solution *p'*.

$$z_9 = \frac{P_g - a_i}{b_i - a_i}. \tag{6}$$

6) The current position of any particle in the swarm is substituted by *p'*.

7) The algorithm will return to Step 4 until the termination condition of particle swarm is fulfilled. Then it will stop calculating and output the results.

4 Reducer optimization design model

In this work, two-grade gear reducer is the object of design study, and the mechanism chart is shown in Figure 1 [12].

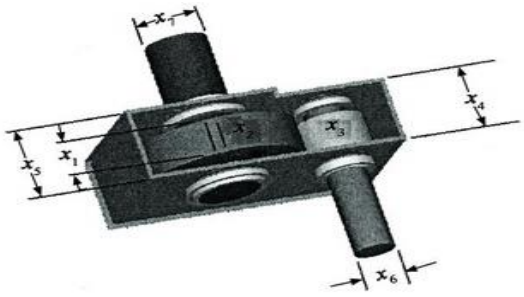

FIGURE 1 Reducer mechanism chart

This problem of design optimization has seven design variables, gear face width x_1, tooth mold x_2, tooth number of small gear x_3, bearing spacing of axis 1 x_4, bearing spacing of axis 2 x_5, the diameter of axis 1 x_6 and the diameter of axis 2 x_7. The ranges of these variables are as below:

$$\begin{aligned} &2.6 \le x_1 \le 3.6, 0.7 \le x_2 \le 0.8, 17 \le x_3 \le 28, \\ &7.3 \le x_4 \le 8.3, 7.3 \le x_5 \le 8.3, 2.9 \le x_6 \le 3.9, \\ &5.0 \le x_7 \le 5.5. \end{aligned} \tag{7}$$

The smallest volume of reducers can be found utilizing objective function.

$$\begin{aligned} \min f1(x) = {} & 0.7854x_1x_2^2(3.3333x_3^2 + 14.933x_3 - \\ & 43.0934) - 1.508x_1(x_6^2 + x_7^2) + \\ & 7.477(x_6^3 + x_7^3) + 0.7854(x_4x_6^2 + x_5x_7^2), \end{aligned} \tag{8}$$

$$A_1 = \left[\left(745x_2^{-1}x_3^{-1}x_4\right)^2 + 16.9\times10^6\right]^{0.5}, \tag{9}$$

$$B_1 = 0.1x_6^3, \tag{10}$$

$$A_2 = \left[\left(745x_2^{-1}x_3^{-1}x_5\right)^2 + 157.5\times10^6\right]^{0.5}, \tag{11}$$

$$B_2 = 0.1x_7^3. \tag{12}$$

There are 11 constraints including tooth bending stress, contact stress, axis transverse deviation, design size, etc. [13,14].

$$g_1(x) = 27x_1^{-1}x_2^{-2}x_3^{-1} - 1 \le 0,$$

$$g_2(x) = 397.5x_1^{-1}x_2^{-2}x_3^{-2} - 1 \le 0,$$

$$g_3(x) = 1.93x_2^{-1}x_3^{-1}x_4^3x_6^{-4} - 1 \le 0,$$

$$g_4(x) = 1.93x_2^{-1}x_3^{-1}x_5^3x_7^{-4} - 1 \le 0,$$

$$g_5(x) = x_2x_3 - 40 \le 0,$$

$$g_6(x) = 5 - x_1x_2^{-1} \le 0,$$

$$g_7(x) = x_1x_2^{-1} - 12 \le 0,$$

$$g_8(x) = 1.9 - x_4 + 1.5x_6 \le 0,$$

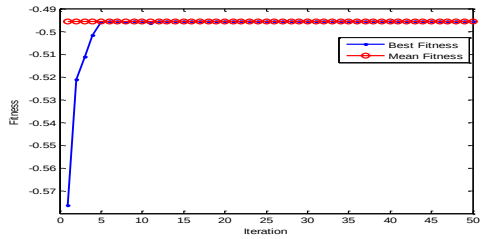
$$g_9(x) = 1.9 - x_5 + 1.5x_7 \le 0,$$

$$g_{10}(x) = A_1B_1^{-1} - 1800 \le 0,$$

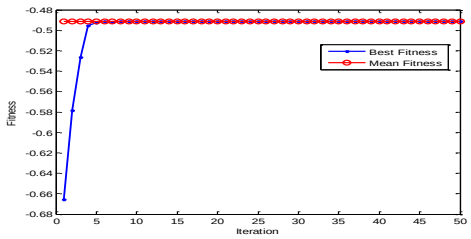
$$g_{11}(x) = A_2B_2^{-1} - 1800 \le 0.$$

5 Simulation

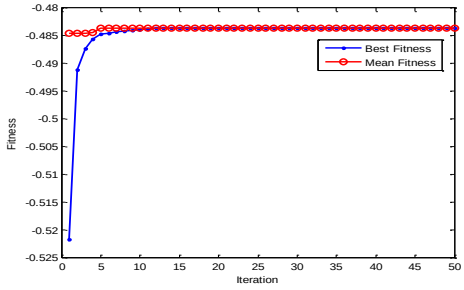
To verify the proposed algorithm, the above mathematical model is optimized and solved with the proposed method. The maximum of iteration is 50; the swarm size 20; *popmin* = –5.12; *popmax* = 5.12; *vmax* = 1; *vmin* = –1. Figure 2 shows the results of simulation.



a) Results of the first operation



b) Results of the second operation



c) Results of the third operation

FIGURE 2 CPSO simulation results

From the optimization results of CPSO algorithm, the design variables are 3.5, 0.7, 17, 7.30, 7.7153, 3.3502 and 5.2867. Figure 2 shows the convergence diagram of CPSO.

To highlight the difference between CPSO and PSO algorithms, parameters are set as follows: the maximum of iterations is 100; the swarm size 20; *popmin* = –5.12; *popmax* = 5.12; *vmax* = 1; *vmin* = –1. Figure 3 shows the convergence comparison before and after the improvement.

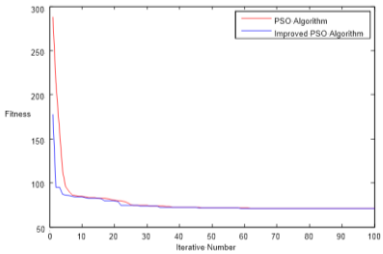


FIGURE 3 Convergence comparison of CPSO and PSO algorithm

In Figure 3, CPSO, with more stable performance, has a significantly faster convergence rate than PSO algorithm, which validates the stability and effectiveness of the proposed algorithm.

6 Conclusions

The work focuses on reducer design optimization. Chaos theory is introduced to particle swarm algorithm due to the problem of local optimum in PSO, thus proposing a CPSO algorithm for optimization design. The steps of CPSO algorithm are elaborated in detail, and the algorithm is combined with a specific case of reducer optimization design for simulation. The results indicate that the algorithm has faster convergence rate than PSO algorithm, so it is of great theoretical and practical value for engineering application.

TV image enhancement technology based on particle swarm optimization

Lifang Yang*, Lin Liu

Chongqing College of Electronic Engineering, Chongqing, 401331, China

Received 1 May 2014, www.cmnt.lv

Abstract

Television images can be blurred and indistinct by noises in the acquisition and transmission process. Traditionally, control parameters of fuzzy enhancement algorithm are manually controlled, which leads to poor enhancement effect and efficiency. In this work, particle swarm optimization (PSO), due to its fewer parameters and global optimization capability, is combined with fuzzy enhancement algorithm for the optimization of fuzzy enhancement parameters. Simulation results show that PSO can make television images clearer and highlight in certain features, thus improving the visual effect of television images.

Keywords: particle swarm optimization, fuzzy enhancement, image processing, fitness function

1 Introduction

Television image can be blurred and indistinct by noises in the acquisition and transmission process. Television image enhancement can improve the quality of television image and highlight certain features, thus making images clearer. There are three categories of image enhancement methods, namely fuzzy processing, frequency domain method and spatial domain method [1-3]. For these methods, transit point and saturation point are manually determined, which limits their application.

2 Image fuzzy processing

In 1981, S.K. Pal, et al [4-6] proposed a new membership function and fuzzy enhancement operator to enhance image contrast, and the algorithm steps are as follows.

Step 1: Due to different purposes of image enhancement, parameters F_e, F_d, $g_{\max}$ in the membership function are adjusted according to Equation (2). The set of μ_{mn} is the fuzzy characteristic plane; g_{mn} the maximum pixel value; F_e exponential fuzzy factor; F_d reciprocal fuzzy factor. These parameters determine the size of fuzziness.

Thus, appropriate fuzzy parameters F_e and F_d can effectively enhance the quality of images. When $\mu_{mn} = G(g_c) = 0.5$, the point calls transit point. Selection of parameters has close relationship with transit point g_c as below [7].

$$G_{mn} = \begin{cases} <0.5 & g_{mn} < g_c \\ =0.5 & g_{mn} = g_c \\ >0.5 & g_{mn} > g_c \end{cases}, \tag{1}$$

F_d can be calculated through Equation (2) when transit point g_c and parameter F_e are determined.

Step 2: The image can be transformed from spatial domain to fuzzy domain by G-transformation.

$$\mu_{mn} = G(g_{mn}) = \left[1 + \frac{g_{\max} - g_{\min}}{F_d}\right]^{-Fe}, \tag{2}$$

$\mu_{mn} \to \mu'_{mn}$, the recursive correction membership of fuzzy enhancement operator, is calculated through Equation (3).

$$T(\mu_{mn}) = \begin{cases} 2\cdot[\mu_{mn}]^2 & 0 \le \mu_{mn} \le 0.5 \\ 1-2\cdot[1-\mu_{mn}]^2 & 0.5 \le \mu_{mn} \le 1 \end{cases}. \tag{3}$$

The key of fuzzy enhancement is that operators increase the membership values μ_{mn} greater than 0.5, and decrease those less than 0.5, thereby reducing the fuzziness. Then fuzzy enhancement operator will create another fuzzy set based on fuzzy set G.

Step 3: Inverse transform G^{-1} generates new gray level g'_{mn} and transforms the image from fuzzy domain to spatial domain [9-10].

$$g'_{mn} = G^{-1}(\mu'_{mn}) = g_{mn} - F_d\left[(\mu'_{mn})^{\frac{-1}{F_e}} - 1\right]. \tag{4}$$

3 Particle swarm optimization (PSO)

3.1 ALGORITHM PRINCIPLE

PSO algorithm was firstly proposed by Kennedy, et al. for simulating the foraging behaviors of birds and achieving optimal results through collaboration and competition between groups. In PSO algorithm, each alternative solution calls a "particle", so after generating initial population, each particle is regarded as a feasible solution. Then fitness is determined by the objective function [11]. Each particle moves in the solution space, and the speed determines the direction and distance of movement.

Typically, the particle will follow the optimal particle and find optimal solution by iteration search. In each process of iteration, the particle follows two extremes to find the optimal solution for itself and the whole population.

3.2 MATHEMATICAL MODEL

For global optimization problem, a set of feasible solutions for the problem (p) is called as a population, where a

feasible solution as a particle, and population size as the number of particles.

$$(P)\min\{f(x): x\in\Omega\subseteq R^n\},\ f:\Omega\subseteq R^n\to R^l. \quad (5)$$

The *n*-dimensional vector $X_i=(x_{i1},x_{i2},...,x_{in})^T\in\Omega$ is the position of *i*-th particle, and vector $V_i=(v_{i1},v_{i2},...,v_{in})^T\in\Omega$ the speed of *i*-th particle. During particles' movement in the search space, its best position is $P_{pi}=(p_{pi1},p_{pi2,}....,p_{pin})^T$. The index number g indicates the best position of all the particles, namely P_g. Thus, the velocity of particles in each iteration and the position evaluation function can be transformed by Equations (6) and (7), respectively [12].

$$v_{id}(t+1)=v_{id}(t)+c_1 rand_1(p_{pid}-x_{id}(t))+ c_2 rand_2(p_{gd}-x_{id}(t)), \quad (6)$$

$$x_{id}(t+1)=x_{id}(t)+v_{id}(t+1), \quad (7)$$

where, $i=1,2,...,m$, $d=1,2,...,n$; $rand_1$ and $rand_2$ are subject to the distribution of $U(0,1)$; learning factors c_1 and c_2 are non-negative constants; for $v_{id}=[-v_{\max},v_{\max}]$, $v_{\max}$ is the speed limit set by users. Iterative algorithm is as follows:

Initialize population: random X_i
Repeat:
  For each particle $i\in[1,S]$
    If $f(X_i)<f(P_i)$
    $P_i=X_i$
  End
  If $f(P_i)<f(P_g)$
    $P_g=P_i$
  End
  Update the position and velocity of particle using Equations (6) and (7)
End
Until termination criterion is satisfied.

4 PSO fuzzy enhancement

4.1 Measurement of fuzzy enhancement

Main purpose of image fuzzy enhancement is to decrease information entropy, namely measuring the effect by comparing the information entropy before and after image enhancement. Entropy is defined in Equation (8).

$$H=-\sum_{i=1}^{256}p_i\log(p_i), \quad (8)$$

where p_i is the normalized histogram. Fuzzy entropy is defined in Equation (9).

$$1+\frac{1}{MN\ln 2}\sum_{i=1}^{M}\sum_{j=1}^{N}\left[S_n(\mu_{ij})\right], \quad (9)$$

where MN is the image size; S_n is Shannon function:

$$S_n=-\mu_A(x_i)\ln(\mu_A(x_i))-(1-\mu_A(x_i))\ln(1-\mu_A(x_i)). \quad (10)$$

4.2 Fitness function

Fuzziness entropy is a parameter describing the effect of image enhancement. Only reflecting the brightness of images, it has low insensitivity to the contrast, so some improvements are needed. The fitness function of improvement is in Equation (11).

$$Fitness(\mu)=\frac{\max(\mu_{ij})-\min(\mu_{ij})}{1+\frac{1}{MN\ln 2}\sum_{i=1}^{M}\sum_{j=1}^{N}\left[S_n(\mu_{ij})\right]}, \quad (11)$$

where, $\max(\mu_{ij})-\min(\mu_{ij})$ is the fuzzy contrast; $\max(\mu_{ij})-\min(\mu_{ij})$ are the maximum and minimum values of fuzzy feature plane, respectively. Larger $\max(\mu_{ij})-\min(\mu_{ij})$ makes the image clearer, while smaller fuzzy entropy Equation (9) makes the image clearer. Therefore, larger fitness function $Fitness(\mu)$ is good for the enhancement effect and image quality.

4.3 PSO FUZZY ENHANCEMENT ALGORITHM

A certain number of populations randomly generate during initialization, and corresponding $Fitness(\mu)$ of each population is calculated to find the maximum $Fitness(\mu)$ in the population. Then the velocity and position of particles can be updated according to PSO algorithm rules. After calculating for a given times of iteration, TV image fuzzy enhancement is conducted on parameters F_e, F_d corresponding to the obtained maximum fitness. The algorithm is as follows.

Step 1: Initialize the particle position and parameters;

Step 2: Calculate the corresponding $Fitness(\mu)$ of each population and compare the historical optimal value of individual particle with that of the population; if current value is superior to historical optimal value, then this value is retained, and the historical optimal value of individual

particle or the whole population will be updated; on the contrary, the historical optimal value is retained;

Step 3: Move particles to a new position according to the updation rules of particle position;

Step 4: If $Iteration < Maxgen$, then end the optimization; conversely, return to Step 2;

Step 5: TV image fuzzy enhancement is conducted with the fuzzy enhancement parameters F_e, F_d corresponding to the obtained maximum fitness $Fitness(\mu)$.

5 Simulation

In order to verify the proposed algorithm, the population size is set to 20, and $c_1 = c_2 = 2$, $v_{\max}$=5. Three pieces of standard test images Lena.jpg, Cameraman.jpg and Baboon.jpg are the test objects for verifying the effect of PSO image enhancement. Results are shown in Figures 2-4.

FIGURE 4 Comparison of the histogram before and after PSO fuzzy enhancement

Results of PSO fuzzy image enhancement prove that proposed algorithm can effectively highlight features of the image and improve visual effect. Besides, efficiency

can be improved by avoiding manual adjustment of parameters, and the optimal fuzzy enhancement parameters are set after ensuring the best quality of images.

6 Conclusions

PSO algorithm, due to its excellent search performance, is combined with image enhancement algorithm for the optimization of fuzzy enhancement parameters F_e, F_d. And appropriate fitness function is built to achieve fuzzy enhancement of television image. Simulation results show that PSO has better effect in image enhancement than traditional methods, so it has certain practical value. Meanwhile, PSO algorithm can achieve self-adaption adjustment of fuzzy enhancement parameters, thus greatly improving the efficiency.

The automatic cutting algorithm of the plastic film based on image processing

Daode Zhang, Yanli Li*

School of Mechanical Engineering, Hubei University of Technology, Wuhan, China

Received 1 July 2014, www.cmnt.lv

Abstract

This paper proposes an algorithm based on image processing to solve the dislocation problem when cutting the edge, which is in the light of the uneven edge and the wrong side phenomenon. First of all, the images of the plastic bag edge captured by the camera are pre-treated; then the image is enhanced by fuzzy contrast enhancement algorithm, which is aim to extract the creases contour; finally the edge of the image is detected used by the Canny operator to get the crease on the edge of plastic bag, the cutter position can be obtained by offset some distance from the creases. The research results show that this algorithm is very effective to solve the dislocation problem when cutting the plastic bag edge automatically.

Keywords: fuzzy contrast enhancement, the Canny operator, edge detection, plastic film cutting

1 Introduction

In the industrial manufacturing field, a lot of sheet products are unable to guarantee the uniformity in the process of operation, the reasons are as follows:

1) The malalignment of the drive roller, roller, idler roller and guiding rollers all produce sheet deviation.

2) In the work process, if the sheet products are uneven and partial load, the sheet side uneven stress will be caused and the sheet offset will be resulted in.

3) The unevenness caused by the operator when they place the sheets and the unevenness of the back sheets' state can all make the sheet deviation.

4) When the sheets are coiled to the end, they have no much weight and roll both ways, which can also make the sheet deviation.

From the top, there many deviation factors in the process of coiling sheets, so adding automatic edge control system is necessary in the coiling process, which realizing the automatic alignment.

The edge mismatch and the wrong side are the problems of the plastic bag cutting in the production line, to address this phenomenon; this paper proposes a plastic film automatic cutting algorithm based on image processing to realize straight edge automatically when cutting the edge in the production line.

2 The preprocessing algorithm of plastic film automatic cutting

2.1 THE SUMMARY OF THE PREPROCESSING ALGORITHM

Image pre-processing is an important part of research based on image algorithm, effective treatment for the image can improve the resolution for the key information of the system,so then the stability and accuracy of the feature extracted will be improved, the pre-treatment technology mainly includes image filtering, image enhancement and object segmentation. The image filtering is to suppress the noise in the image, so as to reduce the influence of noise on the feature of the target and improve the stability of feature extracted; image enhancement is to make the target image more clear in the image, this is the focus algorithm in this paper, which is necessary to extract the feature points; object segmentation is to eliminate the impact of background, and improve the accuracy of feature extracted.

The images obtained from cameras are pre-processed used by the median filtering, fuzzy contrast enhancement and edge detection to get clear target contour [1].

2.2 THE REALIZATION OF THE PREPROCESSING ALGORITHM

1. Image filtering.

The objects processed in this paper is the edge image of plastic film in the production line, which have no much details, the purpose for preprocessing is that the complete edge can be extracted. The median filter is especially suitable for the situation in a strong pepper interference or

***Corresponding author** e-mail: author@domain.com

pulse type interference. Because of the interference values are very different from some of the adjacent gray-scale values of the pixels [2]. Therefore the median results after sorting is to make the interference values and some of the adjacent gray-scale values of the pixels same, which can remove the interference effect [3]. Therefore, the median filter will be taken to remove the original image in this paper.

2. Image enhancement

1) The definition of fuzzy contras t.

In recent years, many scholars devoted to introducing the contrast enhancement into the research of image processing, the concept of fuzzy contrast is introduced according to the fuzzy contrast enhancement algorithm proposed by Li Jiuxian et al.

The definition of fuzzy contrast: in the *M***N* image with *L* level grey-scales, $\mu_{ij} \in [0,1]$ ($i = 1,2,..., M$; $j = 1,2,\ldots, N$), μ_{ij} is the membership of the pixels' grey levels x_{ij} , $\bar{\mu}_{ij}$ is the membership of all the pixels gray mean values in the window, which regards the processed point as the centre, so the fuzzy contrast of the pixel x_{ij} is

$$F = \frac{|\mu_{ij} - \bar{\mu}_{ij}|}{|\mu_{ij} + \bar{\mu}_{ij}|}. \tag{1}$$

In the Equation, $|\mu_{ij} - \bar{\mu}_{ij}|$ is the absolute value of the difference between the membership of the pixels x_{ij} and the membership of its neighbour means, which can express the fuzzy contrast; F is the normalized relative fuzzy contrast, F not only considers the smoothing effects of the spatial neighbourhood averages, but also takes into account the tension of the fuzzy domain contrast [3].

2) The improved fuzzy contrast enhancement algorithm.

The improved algorithm of the image enhancement based on the fuzzy contrast is proposed on the basis of the fuzzy contrast enhancement algorithm in the paper, its realization process is as follows:

① The fuzzy enhancement algorithm based on grayscale use a fuzzy membership function that is a linear, that is:

$$\mu_{ij} = T(x_{ij}) = \frac{x_{ij}}{L-1}. \tag{2}$$

② In the Equation, *L* is the grayscale of the image pixel distribution;

③ Calculate the fuzzy image contrast with the 3*3 window;

④ Do a nonlinear transform for *F* to get

$$F' = \psi(F). \tag{3}$$

The selection of the convex function $\psi(g)$ directly affects the enhancement effect of the fuzzy contrast enhancement, if $|\psi(F) - F|$ is too small, the image details cannot be highlighted; if $|\psi(F) - F|$ is too large, the noise will be revealed.

After repeated experiments, this paper choose the polynomial function:

$$\psi(x) = 4x^3 - 12x^2 + 9x. \tag{4}$$

The following conclusion is obtained through the calculation and the verification: $\psi(x)$ is a convex function ($\psi''(x) = 24(x-1) \le 0, \quad \forall x \in [0,1]$, and $\psi(0) = 0$, $\psi(1) = 1$, $\psi(x) \ge x$.

⑤ Use F' to calculate the pixel gray membership degree and it's gray value after adjustment, the mathematical expressions is:

$$\mu'_{ij} = \begin{cases} \dfrac{\bar{\mu}_{ij}(1-F')}{1+F'} & \mu_{ij} \le \bar{\mu}_{ij} \\ 1 - \dfrac{(1-\bar{\mu}_{ij})(1-F')}{1+F'} & \mu_{ij} > \bar{\mu}_{ij} \end{cases}, \tag{5}$$

$$x'_{ij} = \mu'_{ij}(L-1). \tag{6}$$

⑥ The contrast enhancement method not only enhances the edge region but also sharpens the noise to a certain extent, therefore, the median filtering method is used to eliminate the isolated noise points [4].

In summary, the realization process is still that the image is mapped from the spatial domain to the fuzzy domain first， a local contrast operator is definited in fuzzy domain to represent the absolute value of the difference between the membership of the pixels and the membership of its neighbour means. Then, through the convex function to enhance and amplifier the difference among the neighborhood pixels; finally the image is append back to the spatial domain and is filtered, so as to complete the process of the image enhancement processing.

3) The experimental results and analysis.

Note: The red rectangular box marked in the following chart is the position of plastic film edge, the following enhanced image is enhanced used by the fuzzy enhancement two times in order to extract the feature of the edge folds solely.

FIGURE 1 Before enhancing (green)

FIGURE 2 After enhancing (green)

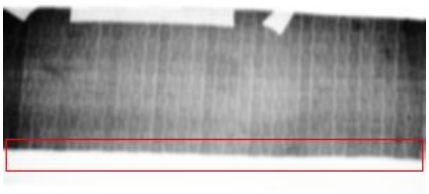

FIGURE 3 Before enhancing (yellow)

FIGURE 4 After enhancing (yellow)

FIGURE 5 Before enhancing (red)

FIGURE 6 After enhancing (red)

FIGURE 7 Before enhancing (white)

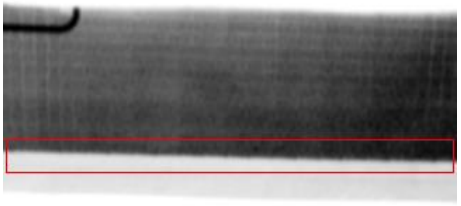

FIGURE 8 After enhancing (white)

By above knowable, after enhancing with fuzzy contrast**(**see Figure 2, Figure 4, Figure 6, Figure 8), the image contrast enhances significantly at the crease and decreases significantly at the edge and background, which lay the foundation for the crease extraction behind.

The image contrast enhancement method is that the spatial domain is enhanced everywhere by enhance the gray difference between neighborhood pixels by locally. But it not only enhances the contrast in the crease region but also sharpens the noise to a certain extent, so the image should be smoothed after enhancing, so as not to affect the quality of the feature extraction.

3. Image edge detection.

Edge detection is the fundamental topic of image processing and computer vision, the study of the human visual system show that the image edge is particularly important and an object can be identified only by a sketchy outline [7].

The essence of edge detection is to extract the boundary between a object and its background image using some algorithm. The process of general edge detection algorithm is that first the smoothing image is obtained by smoothing the original image; and then the image whose edge being enhanced using a variety of algorithms, whose gray levels is 256.

At this time, the flat grey regions disappears and the mutational grey regions remains alone in the image whose gray is enhanced, the 256 levels image is becomed to the binary image after the final threshold segmentation, the edge image is got if the mutant edges are displayed obviously [5].

According to the characteristics of the target image and the requirements of the edge feature, the edge is extracted by Canny operator in this paper, the selection of thresholds should be paid special attention to. After many experiments analysis, the ratio of the Canny operator's two parameter threshold is 2:3 in view of the identification target [6]. The experimental results are as follows:

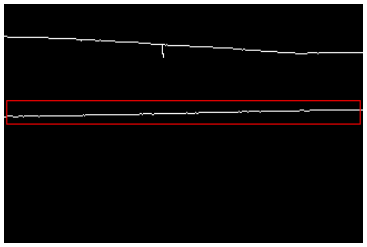

FIGURE 9 Edge detection (green)

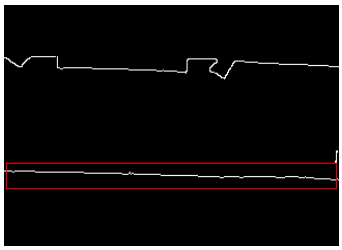

FIGURE 10 Edge detection (yellow)

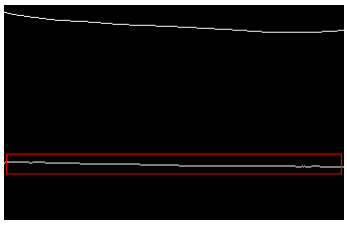

FIGURE 11 Edge detection (red)

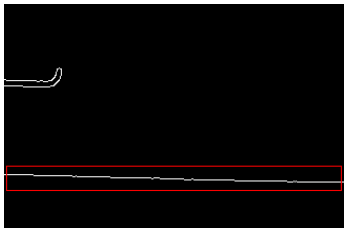

FIGURE 12 Edge detection (white)

3 The automatic cutting algorithm of the plastic film

3.1 THE SUMMARY OF AUTOMATIC CUTTING ALGORITHM

The accurate position of the cutter must be controlled timely in order to realize the automatic slitting of the plastic film. The crease contouring near the edge is obtained by the preprocessing of the plastic film image, including median filtering, image contrast enhancement, edge detection, then the cutter position will be obtained by offsetting some distance according to crease position.

3.2 THE RELIZATION OF THE AUTOMATIC CUTTING ALGORITHM

1. Select the reference position

A reference position needs to be selected as the standard in order to make the cutter regular while cutting the edge. Through the analysis of the plastic film image obtained by the backlight and the camera. The plastic film edge fold position is chose to be the standard position and then the position of the cutter will be obtained by offsetting some distance from the edge if the creases position is got in the image, so as to avoid the uneven edge [8].

2. Obtain the reference position.

A clear outline of the plastic film edge creases is obtained after pretreatment. The next is to determine the position of the crease. The average value of all feature points at the crease is selected as the crease's accurate position.

3. The steps of the algorithm:

1) A region of interest (ROI) is arranged at the crease in the image which includes all feature points in the region of interest.

2) Obtain the coordinate values of each feature point by traversing the ROI area and calculate their average value.

3) Traverse the image again and set a threshold according to the requirements. Then calculate the difference between the coordinate value of each feature point and the average value. If the difference is greater than the threshold, the feature point will be dropped; otherwise it will be remained.

4) Calculate the average coordinate value of each feature point that remained and regard it as the crease position.

5) The cutter position can be obtained by offsetting the distance after getting the standard position of the crease of the plastic film.

6) Select a scale by calibrating the camera and use the scale to transform the pixel position in the image into the actual distance of the controller.

3.3 THE RESEARCH RESULTS AND ANALYSIS

1. The experimental results:

Note: the red rectangular box is the ROI region which contains the crease, the green line is the reference position calculated by the upper algorithm.

FIGURE 13 Crease position (yellow)

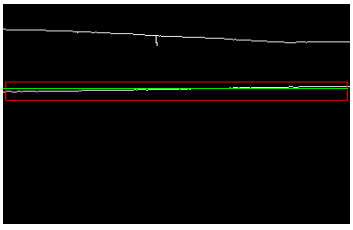

FIGURE 14 Crease position (green)

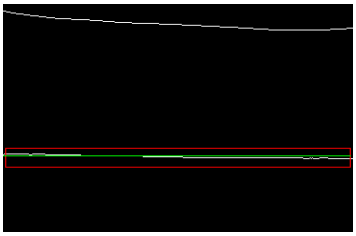

FIGURE 15 Crease position (red)

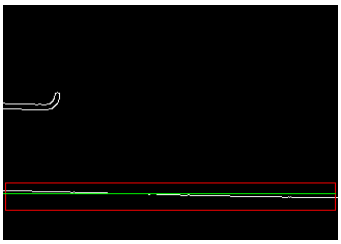

FIGURE 16 Crease position (white)

2. The analysis of the results

The crease position can accurately obtained by the algorithm proposed in this paper. It should be noted that the noise points that offset a long distance from the crease position will affect the accuracy of the algorithm, so it is necessary to eliminate the noise in the third step.

4 Conclusions

This paper aims at the deviation phenomenon of the plastic film automatic cutting in the production line, a lot of manpower and material resources are wasted because of artificial control deviations in the actual production, so the automatic cutting algorithm of the plastic film based on image processing are put forward which resolves the running deviation while cutting the edge and the wrong side phenomenon [9].It has the characteristics of high efficiency and high precision compared with manual visual method. The paper mainly completes the following work:

1. Preprocess the image of plastic film edge. Firstly, make the gray processing for the plastic film; then do smoothing for the processed image; finally the clear edge image can be obtained by the edge detection after getting relatively clear image.

2. Obtain the crease position of the plastic film edge. The clear outlines of the plastic film edge creases are got after pretreatment and the average value of all feature points at the crease is selected as the accurate position of the crease.

3. Get the actual position of the cutter by offsetting some distance from the position of the crease. The location of the cutter can be obtained by making the cutter offset the distance from the crease after getting the standard distance between the edge and the crease; the actual distance of the controller can be obtained by selecting a scale by calibrating the camera and use the scale to transform the pixel position in the image into [10].

The algorithm proposed in the paper also has shortcomings, when the noise points is too much nearby the crease of the plastic film edge image, which is easy to have a great influence on the reference position ,so the preprocessing work is very important.

Abstract

For the problem of long-distance oil and gas pipeline centerline measurement, a method of multi-sensor data fusion using the pipe centerline calculation is presented. The error model is set up by the system of navigation and nonlinear dynamic systems. Using the data of IMU and odometer to calculate the information of pig navigation. All of the errors were calculated by Kalman filter for estimation and compensation. It is concluded that the error for horizontal is 0.35m, the error for vertical is 0.74m for comparison of same pipeline centerline in different inspection time. One feature point is dug to verify the accuracy of the inspection which error is less than 1m. This method is effective for the buried pipeline to perform safely.

Keywords: in-line inspection of long distance pipeline, sensor fusion, inertia navigation, extended Kalman filter, error correction

1 Preface

With the continuous development of domestic oil and gas industry [1], more and more long-distance buried pipelines are used in the transportation of oil and gas products. Due to factors such as geological disasters that will cause pipe displacement or pipe deformation, thus great bending strain will be generated in local pipe body that which will result in additional stress leading to serious instability or material damage to the pipeline. To avoid pipeline failure accidents, Periodically and accurate pipeline centerline positioning measurements are needed in order to determine the specific location of the pipeline, and analysis situations such as pipe displacement, deformation and so on by calculating and comparing historical data, thereby making timely repair focusing on large deformation zone.

Pipeline inspection is the basic method to ensure pipeline safety and In-line Inspection is recognized as the most effective detect means of pipeline safety. Now, large foreign pipeline companies have been able to detect and analyze pipeline position using ILI tools mounted with IMU, due to the monopoly of foreign technology companies on this technology, the domestic research in this area started relatively late, and most research are still in the experimental stage.

In this paper, high-precision inertial measurement unit (IMU) oriented to long-distance gas pipeline centerline measurements was developed, and pipeline centerline location information was calculated through the use of multi-sensor data fusion technology, and a variety of errors generated were corrected by the sensors using the extended Kalman filter, measurement locus error correction was made by referencing Marker point information, and finally get a more accurate pipeline centerline.

2 Measurement systems in ILI

As shown in Figure 1, the Inertial Measurement Unit (IMU) was mounted within the sealed pipeline inspection gauge (PIG) [2-5], in order to the post processing of geographic information data, the master clock in IMU must sync to the GPS clock in above ground marker prior to the inspection. PIG move forward under the driven by the impetus of oil or gas in the pipeline. IMU system is composed of three-axis orthogonal high precision laser gyroscope and three-axis orthogonal accelerometers. Since the inertial navigation system error and odometer offset error accumulated over time, leading to the data migration, so transmitter with the ability to transmit low frequency signal to trigger the above ground GPS marker was also installed besides the odometer. By doing so, using these devices you can do inertial and non-inertial sensor information fusion to calibrate the pipe centerline position calculated from the PIG, Thereby obtaining high-precision pipe centerline data.

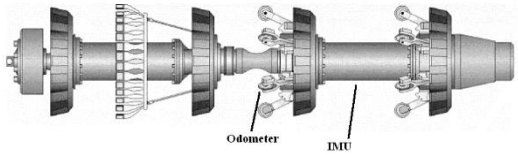

FIGURE 1 Measurement system for In-line inspection of Pipeline centerline

3 Pipeline centerline data fusion algorithm

When run in the pipeline, data collected by all sensors in PIG is stored in the built-in memory. Every movement was collected by the inertial navigation unit including the angular velocity and acceleration in three directions and so on. Odometer measure the mileage of the PIG, thus obtain speed of the PIG to compensate error of the inertial navigation unit [6-10]. The above ground GPS marker receive low frequency signals generated by the transmitter to obtain the exact current location information that error compensation can be done by post-processing. This paper adopt the extended Kalman filter to process the internal attitude, velocity and position information obtained by the PIG, Simultaneously merge the non-inertial odometer data and the ground coordinate data with inertial data [11-13]. The calculation process adopt both the state of forward and backward extended Kalman filter solver system and fix generated system errors. Where in the forward filter is used to calculate $\hat{x}_k$ the current state of the PIG, the backward filter is used to estimate $\delta\hat{x}_k$ the system state amount errors. Therefore the system current revision status is $\hat{x}_{C_k} = \hat{x}_k - \delta\hat{x}_k$. Pipeline centerline data fusion algorithm block diagram is shown in Figure 2.

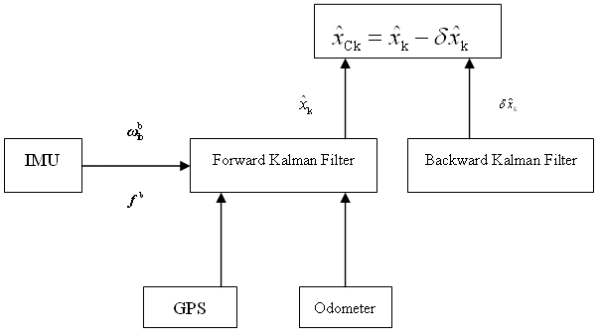

FIGURE 2 Data fusion algorithm diagram of pipeline centerline

3.1 INERTIAL NAVIGATION ALGORITHM

Strapdown inertial navigation system (SINS) and the PIG speed, position dynamic equations are as follows:

$$\dot{V}_e^n = C_b^n f^b - (2\omega_{ie}^n + \omega_{en}^n) \times V_e^n + g_l^n, \tag{1}$$

$$\dot{q} = \frac{1}{2} q \otimes \omega_{nb}^b, \tag{2}$$

$$\dot{L} = \frac{v_N}{(R_N + h)}, \tag{3}$$

$$\dot{l} = \frac{v_E}{(R_E + h)\cos L}, \tag{4}$$

$$\dot{h} = -v_D, \tag{5}$$

where $V_e^n = [v_N \ v_E \ v_D]^T$ is the velocity vector of the PIG, g_l^n is the gravitational acceleration, $q = [q_0 \ q_1 \ q_2 \ q_3]^T$ is the four elements, f^b is collected force ratio value, L and l are respectively latitude and longitude h is the elevation. R_E and R_N are the earth radius under the WGS1984 geography coordinator system.

C_b^n is the transmit matrix from the PIG carrier coordinate system into the local navigation coordinate system that can be obtained by calculating the four elements [14-17], that is:

$$C_b^n = \begin{bmatrix} q^2{}_0 + q^2{}_1 + q^2{}_2 + q^2{}_3 & 2(q_1q_2 - q_0q_3) & 2(q_1q_3 - q_0q_2) \\ 2(q_1q_2 + q_0q_3) & q^2{}_0 - q^2{}_1 + q^2{}_2 - q^2{}_3 & 2(q_2q_3 - q_0q_1) \\ 2(q_1q_3 - q_0q_2) & 2(q_2q_3 + q_0q_1) & q^2{}_0 - q^2{}_1 - q^2{}_2 + q^2{}_3 \end{bmatrix}, \tag{6}$$

where ω_{ie}^n is the Earth angular velocity in the navigation reference, ω_{en}^n is the angular rate relative to the Earth navigation reference, ω_{nb}^b is the platform's angular rate of the navigation system. These angular rate expressions are:

$$\omega_{ie}^n = \left[\Omega\cos L \quad 0 \quad -\Omega\sin L\right]^T, \tag{7}$$

$$\omega_{en}^n = \left[\frac{v_N}{R_E + h} \quad -\frac{v_N}{R_N + h} \quad -\frac{v_N}{R_E + h}\tan L\right]^T, \tag{8}$$

$$\omega_{nb}^b = \omega_{ib}^b - C_n^b\left(\omega_{ie}^n + \omega_{en}^n\right). \tag{9}$$

Constant Ω is the Earth's rotation angular rate. Vector $\omega_{nb}^b = [\omega_{nbx}^b \ \omega_{nby}^b \ \omega_{nbz}^b]^T$ is the angular rate of the carrier system to the Geography coordinate system using to update the attitude angle is system. The inertial navigation coordinates of the pipeline centerline can be calculated by integrating all the data in Equations (1)-(9). As the pure inertial navigation results has an error accumulation characteristic, and therefore require additional auxiliary sensor information to eliminate the accumulated error.

3.2 DEAD RECKONING ALGORITHM

Dead reckoning algorithm utilizes the carrier's heading and attitude angle provided by the IMU with odometer speed to calculate the carrier's relative position to the starting point. Assuming $v_m^b = [0 \ v_m \ 0]^T$ is the projection of the odometer output speed in the carrier

coordinate system, where the speed of the navigation odometer system can be expressed as: $v_m^n = C_b^n v_m^b = [v_{mN}^n \quad v_{mU}^n \quad v_{mE}^n]^T$, then the position information calculated using dead reckoning algorithm is:

$$\begin{cases} \dot{L} = v_{mN}^n / (R_M + h) v_m^n \\ \dot{\lambda} = v_{mE}^n \sec L / (R_M + h). \\ \dot{h} = v_{mU}^n \end{cases} \tag{10}$$

3.3 ERROR EQUATION OF NAVIGATION AND INERTIAL SENSORS

Run track of the PIG can be obtained by linearization the speed equation, and the speed error can be expressed as:

$$\delta \dot{v}^n = f^n \times \Psi + C_b^n \delta f^b - (2\omega_{ie}^n + \omega_{en}^n) \times \delta v^n - (2\delta\omega_{ie}^n + \delta\omega_{en}^n) \times v^n - \delta g_l, \tag{11}$$

$$\dot{\Psi} = -\omega_{in}^n \times \Psi + \delta\omega_{in}^n - C_b^n \delta\omega_{ib}^b, \tag{12}$$

where: $\delta v^n = [\delta v_N \quad \delta v_E \quad \delta v_D]^T$ is speed error vector of reference navigation $\Psi = [\delta\alpha \quad \delta\beta \quad \delta\gamma]^T$ describes the inclination and azimuth vectors, which can be approximately expressed as a smaller angle offset.

This gives a navigation error in the navigation coordinates:

$$\delta L = \frac{1}{R_N + h} \delta v_N - \frac{v_N}{(R_N + h)^2} \delta h, \tag{13}$$

$$\delta l = \frac{1}{(R_E + h)\cos L} \delta v_E + \frac{v_E \sin L}{(R_E + h)\cos^2 L} \delta L - \frac{v_E \sin L}{(R_E + h)^2 \cos L} \delta h, \tag{14}$$

$$\delta h = -\delta v_D, \tag{15}$$

where δL, δl and δh are the latitude, longitude, and elevation error.

3.4 ERROR EQUATION OF NON-INERTIAL SENSORS

Data fusion algorithm is used to process the inertial unit data and other non-inertial sensors data, in order to decrease inertial error brought by inertial navigation. The non-inertial sensors here are odometer and above ground GPS marking boxes. Continuous odometer data can be converted into an average speed used to represent v_m, the instantaneous speed of PIG. Assuming odometer ratio error factor is k_{fe}, and then the speed of the PIG can be expressed as:

$$v_m^b \approx v_x^b - k_{fe} v_x^b, \tag{16}$$

where v_x^b is the velocity component in the *x* direction of the PIG, v_v^n is the white Gaussian noise with zero mean generated in the measurement of the velocity. Therefore, error rate in the navigation frame can be expressed as:

$$\delta v_m^n = \hat{v}^n - C_b^n v_m^b = \delta\hat{v}^n + v_m^b k_{fe} + v_v^n. \tag{17}$$

The above ground marker (AGM) is used to receive the low frequency signal of transmitter, and can provide position information of the PIG. The position error model is:

$$\delta p_m = \hat{p}^n - p_m^n = \delta\hat{p}^n + v_p, \tag{18}$$

$\hat{p}^n$ is the estimated location coordinates (latitude and longitude, elevation), p_m^n is location coordinates vector, v_p is the zero mean Gaussian white noise generated by measuring the position.

3.5 EXTENDED KALMAN FILTER

The error of inertial navigation results is an accumulating amount over time, and the error will greatly affect the output accuracy of navigation and positioning system. Navigation and positioning algorithm is an iterative calculation, If the calculation errors cannot be corrected, Navigation and positioning system will not accurately reflect the operation situation of the PIG. So, after analysis all the errors generated by the system extended Kalman filter is used for the system error correction.

As the real-time state of the system is obtained by a series of non-linear formula, so the extended Kalman filter is used to calculate. The basic idea of Extended Kalman Filter is to distribute processing first, and then does the global integration; obtain global estimates based on all observations information data, it integrates speed, location measurement of INS and odometer, above ground GPS location marker boxes information. Extended Kalman filter is described by the following equation:

1) state and output equations

$$x_{k+1} = f(x_k, u_k, k) + w_k, \tag{19}$$

$$z_k = h(x_k, k) + v_k. \tag{20}$$

2) the state estimates partial derivative matrix after each calculation the time interval ($t = kT$) by the filter is:

$$A_k = \frac{\partial f(x_k, u_k, k)}{\partial x_k}\Big|_{x=\hat{x}_k}, \quad H_k = \frac{\partial h(x_k, k)}{\partial x_k}\Big|_{x=\hat{x}_k}. \tag{21}$$

3) filter update equation:

$$K_k = P_k H_k^T (H_k P_k H_k^T + R)^{-1}, \tag{22}$$

$$\hat{x}_{k+1} = f(\hat{x}_k, u_k, k) + K_k(z_k - h(\hat{x}_k, k)), \tag{23}$$

$$P_{k+1} = A_k (I - K_k H_k) P_k A_k^T + Q , \tag{24}$$

where v_k is the measurement error vector, z_k is the measurement vector.

$$\begin{bmatrix} z_1 \\ z_2 \\ z_3 \\ z_4 \\ z_5 \\ z_6 \end{bmatrix} = \begin{bmatrix} 0\,0\,0\,0\,1\,0\,0\,0\,0\,0 \\ 0\,0\,0\,0\,0\,1\,0\,0\,0\,0 \\ 0\,0\,0\,0\,0\,0\,1\,0\,0\,0 \\ 0\,0\,0\,0\,0\,0\,0\,1\,0\,0 \\ 0\,0\,0\,0\,0\,0\,0\,0\,1\,0 \\ 0\,0\,0\,0\,0\,0\,0\,0\,0\,1 \end{bmatrix} \begin{bmatrix} q_0 \\ q_1 \\ q_2 \\ q_3 \\ v_N \\ v_E \\ v_D \\ L \\ l \\ h \end{bmatrix}_k + \begin{bmatrix} \delta_{v_N} & 0 & 0 & 0 & 1 & 0 \\ 0 & \delta_{v_E} & 0 & 0 & 0 & 1 \\ 0 & 0 & \delta_{v_D} & 0 & 0 & 0 \\ 0 & 0 & 0 & \delta_L & 0 & 0 \\ 0 & 0 & 0 & 0 & \delta_l & 0 \\ 0 & 0 & 0 & 0 & 0 & \delta_h \end{bmatrix} \begin{bmatrix} v_{v_N} \\ v_{v_E} \\ v_{v_D} \\ v_L \\ v_l \\ v_h \end{bmatrix}_k . \tag{25}$$

By Equation (19)-(25), a system state equation was obtained from the system error model, which establishes the relationship between the speed, position error and the other error amount, between the previous error amounts. All the errors can be estimated through the forward Kalman filter, and then obtain the values of each state amount.

3.6 THE BACKWORD KALMAN FILTER

Filtering relevant information can be saved in the forward filtering and the error of each estimate can be got in the backward Kalman filtering, calibrated result $\hat{x}_{C_k}$ can be calculated finally. The backward Kalman filter using the following formula [18-20].

Assuming the estimated value and variance of each state are $\bar{x}_{k+1}$ and $\bar{p}_{k+1}$ at time $k + 1$, then: single stepping state predictive value:

$$\hat{x}_{k+1,k} = \phi_{k+1,k} \bar{x}_k . \tag{26}$$

Single stepping state prediction error covariance matrix

$$\hat{p}_{k+1,k} = \phi_{k+1,k} \bar{p}_k \phi_{k+1,k}^T + \Gamma_{k+1,k} Q_k \Gamma_{k+1,k}^T . \tag{27}$$

Time filter gain matrix at time *K*:

$$J_k = \bar{p}_k \phi_{k+1,k} (\phi_{k+1,k} \bar{p}_k \phi_{k+1,k}^T + \Gamma_{k+1,k} Q_k \Gamma_{k+1,k}^T)^{-1} = \hat{p}_k \phi_{k+1,k} \bar{p}_{k,k-1}^{-1} . \tag{28}$$

State estimation error at time *K*:

$$\delta \hat{x}_k = J_k (\hat{x}_{k+1} - \hat{x}_{k+1,k}) . \tag{29}$$

The estimated status value at time *K*:

$$\hat{x}_{C_k} = \hat{x}_k - \delta \hat{x}_k . \tag{30}$$

4 Field validation and data analysis

4.1 FIELD TEST EQUIPMENT AND PERFORMANCE INDICATORS

Most domestic oil pipeline are heating transportation, and pass through mountain, hills, rivers and other complex environmental areas, the technical and safety requirements of electrical equipment of which is extremely strict. To be able to safely detect the actual pipeline, IMU should not only meet the technical performance, but also consider the actual situation of the pipe and the external environment in order to ensure the detection successfully and safely conducted. Technical performances of inertial devices used in the field test are shown in Table 1; the environmental targets need to meet are shown in Table 2.

TABLE 1 Characteristic of Sensors

Sensor	Characteristics	Magnitude
Gyroscope	bias	<0.01°/h
	Random walk	0.002° / $\sqrt{h}$
Accelerometer	Bias Stability	<50ug
	Scaling factor	<50ppm
Odometer	Scaling factor	<0.3%
	White noise	<0.1m/s
Landmark	White noise	<±1m

TABLE 2 Characteristics of Circumstances

Characteristics	Magnitude
Temperature	0~60℃
Vibration	6g（RMS）
Impaction	30g
Pressure	3MPa

IMU inertial navigation unit is mounted on the PIG shown in Figure 1. The data collected by the system is stored in the built-in memory. The data in the built-in memory is downloaded at the end of the field test via the communication cable and then carry out post-processing.

4.2 DATA ANALYSIS

Two centerline measurement field tests were conducted on one crude oil pipeline of PetroChina Pipeline Company, and the two tests' relevant information are basically the same, here use the correlation results of the second trial as test instructions. Throughout the test, the PIG runs at an average speed of 1.16m/s in the pipe, the maximum speed is 1.27m/s, and the entire trial took about 54 hours and 15 minutes. An above ground GPS Marker is set just on the ground above buried pipeline centerline every 2Km to obtain the time that PIG pass through the Marker to perform error correction on the measurement results.

Integrate the IMU data, odometer data and the above ground GPS Marker data using the data fusion algorithm describes in this article can obtain a more accurate pipeline centerline. The following uses the first 30km trial data as an example of the data analysis, Figures 3 and 4 show the track and height of the pipeline centerline during inspection obtained by the PIG. As can be seen from the figure, the height of pipeline changes significantly and fluctuated considerably, while the PIG's speed traveling in the pipe is more stable and run in a relatively stable state.

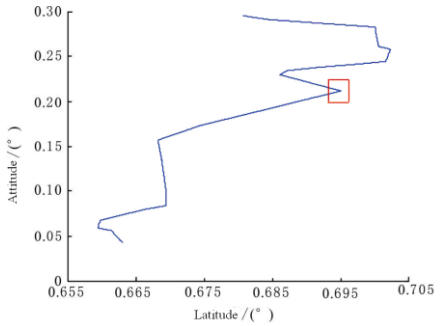

FIGURE 3 Curve of pipeline for measurement of In-line inspection

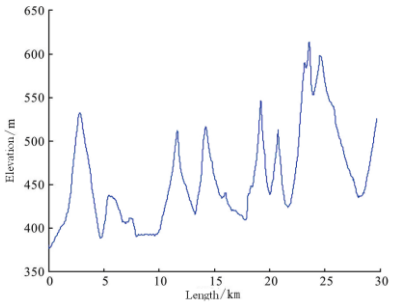

FIGURE 4 Height of the curve for measurement of In-line inspection

The twice measurement results of this pipe section were comparative analysed to calculate the repeatability between the two measurements. Since using 300m as an error analysis unit that there will be a total of 100 points in the first 30Km. As can be seen from Figures 5 and 6, the error curve and the error distribution of the two measurements as follows, the error between the two obtained pipeline centerline is small. The error statistics shows that the error in the horizontal direction is 0.35m (1σ), while in the height direction is 0.74m (1σ).

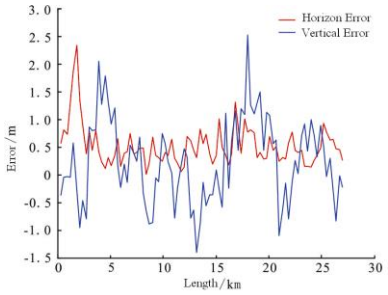

FIGURE 5 Horizon and height error for two measurements

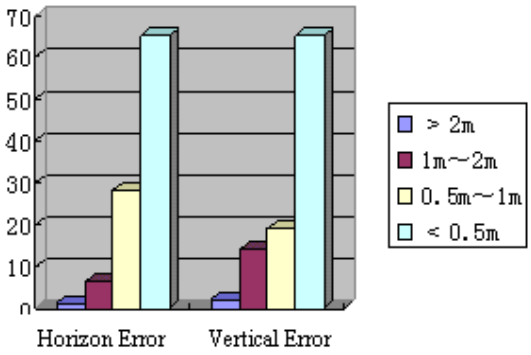

FIGURE6 Horizon and height error of the measurement distribution for two measurements

4.3 EXCAVATION VERIFICATION OF FEATURE POINTS

To further validate the accuracy of the measurement results, select the middle point of the right bend in Figure 3 as excavation verification point to verify the accuracy of IMU measurements. The location point calculated by IMU measurement result locates 0.4 meters downstream the target point while locates 0.7 meters right side in the vertical direction of the oil flow. This error is equal to the analysed repeatability error between two measurements in last section. From this we can see that the accuracy of IMU can achieve to less than 1m which meets the accuracy requirements in actual work.

5 Conclusion

1) This paper studied a buried pipeline centerline measurement method based on inertial navigation technology and multi-sensor data fusion, integrating inertial navigation systems, odometer data and ground GPS data to calculate the coordinates of buried pipeline centerline;
2) Through the use of high-precision, strong impact vibration resistance devices, improved system's security, reliability, and successfully applied to the site inspection of actual crude oil pipeline;
3) All the errors generated in the inspection process were effectively inhibited by this method and the accuracy of the measurement results was improved. Through repeatability error analysis between the two measurements and feature points excavations verify shows the actual positioning accuracy of PIG was within 1m.
4) The above ground GPS marker boxes trigger rate is not high due to factors such as the depth, conductivity of soil and so on. To improve GPS Marker boxes trigger rate then further improve positioning accuracy, a suitable ground tracking technology should be further researched.

A hand gesture interaction system based on Kinect

Weiqing Li*, Zehui Lu, Shihong Shen

School of Computer Science & Engineering, Nanjing University of Science & Technology, Nanjing, China, 210094

Received 1 October 2014, www.cmnt.lv

Abstract

We introduce a hand gesture interaction system using Kinect, which takes advantage of real-time dynamic motion capture, image recognition and so on, so that people can interact with computer by natural hand gestures. Five kinds of gesture are defined and can be recognized by the system. Kinect-based hand movements and gesture recognition algorithm is studied. A method for hand area image segmentation from the depth map is proposed, using the information of hand joints in skeleton map. We realized a hand gesture recognition algorithm with SVM and tested its stability and robustness. Finally, experimental results verified the feasibility of the algorithm, and a hand gesture interactive demonstration is implemented.

Keywords: hand gesture recognition, Kinect, SVM, interaction

1 Introduction

With the development of computer vision technology, interactive computer-based vision systems have gradually developed. The traditional interaction methods such as mouse and keyboard have been unable to play a facilitating role, in some specific areas. The interaction method based on computer vision will be a very good way. The hand gesture recognition based on computer vision is a hot spot of human-computer interaction research [1]. The hand gesture interaction is rich in expression and contains a lot of information, for example we can get lots of information through different gestures, different locations, and different directions. It is a much natural interaction method.

The Kinect sensor is a horizontal bar connected to a small base with a motorized pivot, and is designed to be positional lengthwise above or below the video display. The device features an RGB camera, depth sensor and multi-array microphone running proprietary software, which provide full-body 3D motion capture, image recognition and voice recognition capabilities [2]. It was developed at Microsoft Research Cambridge in collaboration with Xbox. Kinect gives completely hands-free control of electronic devices possible by using an infrared projector and camera and a special microchip to track the movement of objects and individuals in three dimensions.

In this paper, we propose a hand gesture interaction system based on Kinect. We define some hand gestures that can be used to interact with the system. Then we study the hand movement recognition algorithm, and set up a method of hand area image segmentation from the depth map background by using the information of hand joints in skeleton map. Also, we realize a hand gesture recognition algorithm with SVM. Finally some experimental results verify the validity of this algorithm.

2 Hand gesture definition

The basic idea of Kinect is to segment a single depth image into a dense probabilistic body part, labelling as a per-pixel classification task and then estimate this signal to give high-quality proposals for the 3D locations of body joints. And Kinect's depth sensor consists of an infrared laser projector combined with a monochrome CMOS sensor, which captures video data in 3D under any ambient light conditions. The sensing range of the depth sensor is adjustable, and the Kinect software is capable of automatically calibrating the sensor based on the player's physical environment, accommodating for the presence of furniture or other obstacles [3]. In order to recognize hand gestures and interact with the system, we define 5 gestures, show in Table 1.

TABLE 1 Hand gesture definition

Gesture	Meaning	Gesture	Meaning
Keeping single finger straight for 1 second	Left click	Spreading out the fingers and keeping moving at the same time	Mouse move
Keeping fist for 1 second	Right click	Spreading out the arms to the two sides	Zoom in
Holding the fingers straight and closing them	Click down	Making hands close to the chest	Zoom out
Spreading out the fingers on one hand for 1 second	Click release	Waving the right hand to right quickly	Forward
Putting hands over the head	Full screen	Waving the right hand to left quickly	Backspace

3 Hand gesture recognition

In this section we will introduce two algorithms: hand movements tracking algorithm and hand gesture recognition algorithm with the depth map, let's discuss them in detail.

The hand movements refer to the gestures of waving our hands to right or left, up and down. We use these gestures to control the system such as zoom in, zoom out, full screen, forward, backspace and so on.

The hand gesture means the finger postures, such as making a fist, spreading out fingers and so on [4,8]. Kinect can't recognize the shape of fingers and palm at present, so we propose a hand gesture recognition method using SVM. The process is shown in Figure 1.

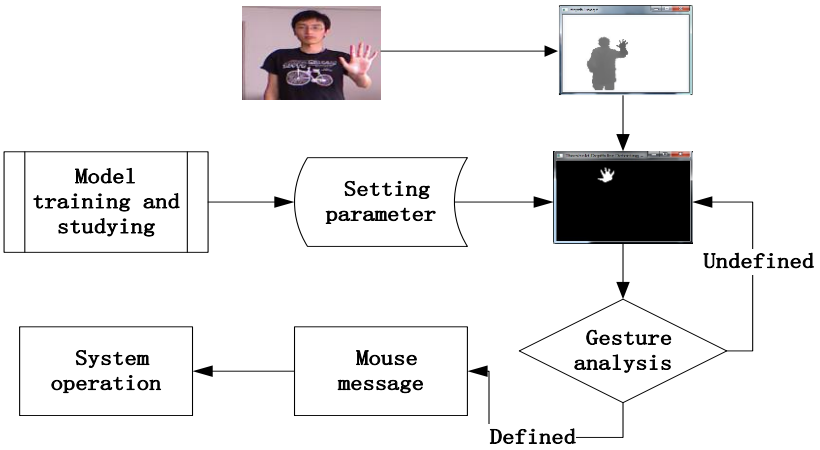

FIGURE 1 Hand gesture recognition process

3.1 HAND MOVEMENTS TRACKING

3.1.1 Joints data pre-processing based on the continuous space-time tracking

Kinect can get three kinds of images, they are color map, depth map and skeleton map. The skeleton map is consisted of twenty joints including our hand joints. The camera's coordinates are (0,0,0), the right direction is the positive direction of the x axis, the upward direction is the positive direction of the y axis and the positive direction of the z axis is facing to the operator. So every frame Kinect captures all the joints' three-dimensional coordinates.

Based on continuous space-time tracking of hand movements' characteristic [5], the movement tracking method can be separated into two parts. The first part is called preprocessing, as Kinect is capable of simultaneously tracking up to six people, but in fact the system can be operated just by one person. So the problem is whose hand gesture should be recognized when there are many people stand before Kinect. We use the bubble sorting algorithm for the head's coordinate on the z axis (if the people is not exist, we will set a maximum value for the coordinate). Kinect will consider the person who has the minimum coordinate as the operator and recognize his gesture.

The second part is called hand movement tracking. We set a sliding window and store 20 frames continuous skeleton image, then the three-dimensional coordinate data extraction and analysis. The sliding window slides backwards and inserts the next frame, the first frame will be deleted. Let's discuss the tracking method in next chapter.

3.1.2 Hand movements' characteristic definition

Hand gesture definition means the gesture's specific function, such as waving right hand to right means going to the next page, waving right hand to left means going back, waving left hand to left and right hand to right at the same time means zoom in, etc. If the left hand thrusts forward and then moving right hand, it means we have clicked the mouse and controlling the movement of the mouse now. These are defined as follows:

1. The definition of click. We get a series of values on the z axis, such as $z_1, z_2, ..z_n$, in a period of time (such as 3 seconds). If $z_1 \succ z_2 \succ ..z_n$ and $\delta_1 \succ z_1 - z_n \succ \delta_2$, then the system will consider the left hand has done the click action. The thresholds δ_1 and δ_2 can be set different values according to different conditions.

2. The definition of forward. We can get a series of right hand's two-dimensional coordinate values such as $x_1, x_2, ..x_n$ and $y_1, y_2 ..y_n$ in a period of time (such as 3 seconds). If $x_1 \prec x_2 \prec x_3 \prec ... \prec x_n$, $x_n - x_1 \succ \delta$ and $\max(y_i) - \min(y_j) < \varepsilon$, then the system will consider the operator has done the forward gesture. The thresholds δ and ε can be set different values according to different conditions. $\max(y_i)$ and $\max(y_j)$ represent the maximum and minimum value on the y axis when we wave our hands.

3. The definition of zoom in. We can get a series of values such as $R(x_1), R(x_2),...,R(x_n)$, $R(y_1), R(y_2),...,R(y_n)$, $L(x_1), L(x_2),..., L(x_n)$ and $L(y_1), L(y_2),..., L(y_n)$. If $L(y_1), L(y_2),...,L(y_n)$, $R(x_1) \prec R(x_2) \prec ... \prec R(x_n)$ and these values satisfy with the formulas as follows:

$$\left|R(x_n) - R(x_1)\right| \succ \delta, \tag{1}$$

$$\left|\max(R(y_i)) - \min(R(y_j))\right| \prec \varepsilon, \tag{2}$$

$$\left|L(x_n) - L(x_1)\right| \succ \delta, \tag{3}$$

$$\left|\max(L(y_i)) - \min(L(y_j))\right| \prec \varepsilon. \tag{4}$$

Then the gesture will be considered as zoom in. $R(x)$ and $R(y)$ are right hand's coordinates (x, y) . $L(x)$ and $L(y)$ are left hand's coordinates (x, y) . We can set different values for and according to different conditions. $\max(R(y_i))$ and $\min(R(y_j))$ represent the maximum and minimum value on the y axis when we wave right hand.

3.2 HAND GESTURE RECOGNITION BASED ON DEPTH MAP

3.2.1 Hand area image segmentation assisted by skeleton map

Except the skeleton map, Kinect can also get colour map and depth map. We can recognize the hand gestures with these two kinds of maps. The colour map has the advantage of clearness, but it is susceptible to interference and only contains the information in two dimensions. On the other hand, the depth map's resolution is lower than colour map, but contains information of 3D. We propose a method of hand seg-mentation from the depth map background using the information of hand joints in skeleton map.

As Kinect can track our hands' coordinates with the help of skeleton map, so we can easily get the precise location of our hands in the skeleton map. The hand's location can be mapped to the depth map with the help of the pixel ratio between the skeleton map and the depth map. As the depth map contains the three-dimensional information, so we can realize the segmentation from the depth map background according to the depth information [6].

For the image segmentation, threshold has a big influence. The definition of depth threshold is:

$$\psi = \min(z) + \delta, \tag{5}$$

$\min(z)$ represents a point's coordinate on the z-axis which is the nearest point to the camera of our body. δ is a experimental value, the range of the value is $\min(z)$ to ψ . This is the most precise value of the palm's location. In our experiment, we set 5cm for δ . In this case, we get the hand segmentation image as Figure 2.

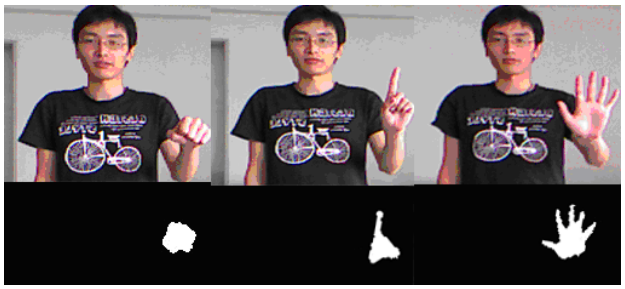

FIGURE 2 Hand area segmentation

3.2.2 Gesture recognition algorithm using SVM

SVM is a classifier, it is firstly proposed by Cortes and Vapnik in 1995. Compared with the traditional method, SVM doesn't depend on the selection of the model. It shows many special advantages in resolving the small sample, nonlinear pattern recognition [7]. The SVM algorithm references kernel function, and then the algorithm converts the practical problem to a high dimensional feature space through the nonlinear transformation. It creates the linear discriminate function in high dimensional space to realize the nonlinear discriminate function in the original space, its particular characteristics can certify the sys-tem has good generalization ability. In addition, SVM solved the dimension problem skillfully. Its algorithm complexity has nothing to do with the dimension of the sample, so the SVM classifier can adapt to the classification problem of different dimensionality. In this section, we use the SVM classifier to recognize the hand gestures according to the limitation of the sample and the accuracy of the recognition.

Firstly, in order to get the contour of the hand, we denoise and smooth the hand image which segmented from the depth map, and remove some isolated points. Then we will calculate some characters of the gesture, such as Circularity:

$$Circularity = \frac{L^2}{4\pi \times AL}. \tag{6}$$

This characteristic describes the closeness between the gesture and circle, the closer the value to one, the more like the circle. L represents the perimeter of the contour of the hand. A represents the area of the contour of the hand. The distribution graph is about the gestures' circularity. We can find that the circularity of the fist most close to one and the circularity of the palm is the biggest. Because the palm's opening in varying degrees so the value of L will be different and then lead to the fluctuant.

Filling Ratio:

$$FillingRatio = \frac{A}{A - R}. \tag{7}$$

This characteristic describes the area ratio of the hand occupies in the rectangle outside. The bigger of the value, the more gathered of the gesture. *A* - *R* represents the area of the smallest rectangle outside. The distribution graph is about the gestures' filling proportion. We can find from the graph that the fist's value is the biggest, and it means the fist has the highest polymerism.

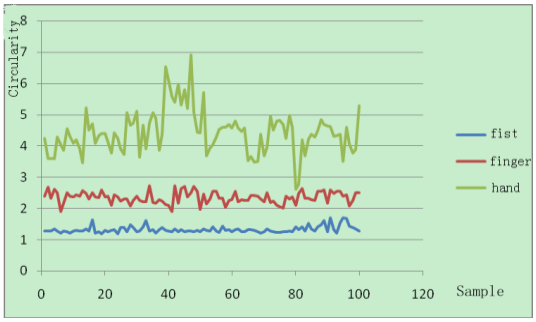

FIGURE 3 Circularity of gestures

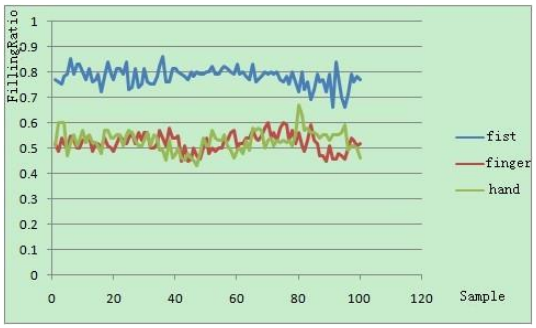

FIGURE 4 Filling ratio of gestures

Perimeter Ratio:

$$PerimeterRatio = \frac{L}{L-C}. \tag{8}$$

This characteristic describes the ratio between the perimeter of the contour of the hand and the mini-mum circumference of the circle outside, the bigger of the value, the more opening of the gesture. *L_C* represents the circumference of the smallest circle outside. The distribution graph shows three gesture's perimeter ratio. We can find that the palm's perimeter ratio is much bigger than the other two gestures.

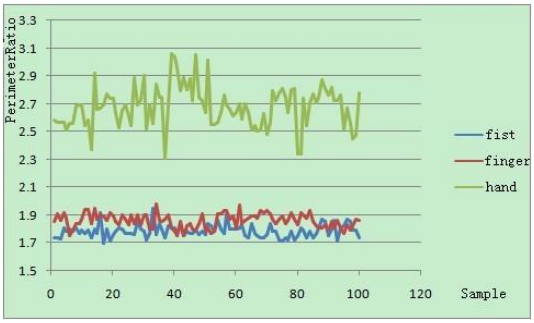

FIGURE 5 Perimeter ratio of gestures

4 Experiment

4.1 HAND MOVEMENTS RECOGNITION EXPERIMENT

Moving the right hand slowly means the movement of mouse, and moving the right hand to right or left quickly means going forward or going back. So it is necessary to set a threshold, if we want to distinguish the forward gesture from the back gesture. Because when we wave our arms, its orbit is an arc, so the co-ordinate on the z axis keeps changing all the time. In order to prevent from confusing with the click behaviour, we should set a threshold on the z axis. The specific value can be changed with different conditions, the method as follows:

As to the click gesture, δ_1 is set to 0.2 and δ_2 is set to 0.1, it means the left hand's range of movement should between 10cm and 20cm in a period of time, then the gesture will be recognized as click.

As to the forward gesture, δ is set to 0.3 and ε is set to 0.1, it means the right hand's range of movement should greater than 30cm and the amplitude should less than 10cm in a period of time, then the gesture will be recognized as going forward.

The gesture of zoom in has the same thresholds with the forward gesture, as the gesture of zoom in includes the forward gesture, so we introduce the priority in order to distinguish these two kinds of gestures. The gesture of zoom in has a higher priority than the forward gesture and the gesture of zoom out has a higher priority than the back gesture.

We perform 100 click operations and 100 forward operations with different thresholds, the recognition rates are showed in Table 2 and Table 3. When we perform the forward gesture, for the ε, a higher value is better, in order to have a better understanding of the gesture, ε should not get a too large value, 0.1 is a right value.

TABLE 2 Threshold of click operation

Threshold	$\delta_1 = 0, \delta_2 = 0.1$	$\delta_1 = 0.1, \delta_2 = 0.2$	$\delta_1 = 0.2, \delta_2 = 0.3$	$\delta_1 = 0.3, \delta_2 = 0.4$	$\delta_1 = 0.4, \delta_2 = +\infty$
Recognition rate	0.73	0.91	0.77	0.53	0.12

TABLE 3 Threshold of forward operation

Threshold	$\delta = 0.1$	$\delta = 0.2$	$\delta = 0.3$	$\delta = 0.4$

5 Conclusions

In this paper, we introduce a hand gesture interaction system based on Kinect. We get the hand gesture image by Kinect, then the system will analyse and recognize both the movement and the gesture. In order to recognize the gesture precisely, we design an algorithm based on SVM. Also, we map gestures to mouse events to interaction with the computer. From the experimental results, we notice that the algorithm has well reliability and strong robustness.

On the other hand, this gesture interaction system has some work to go on, such as we need more gesture definitions and improve the system's sensitivity. These will be considered as future work.

Robust volume data watermarking based on perceptual hashing

Yujia Li, Jingbing Li*

College of Information Science and Technology, Hainan University, Haikou, China, 570228

Received 1 March 2014, www.cmnt.lv

Abstract

This paper proposed a perceptual hashing algorithm of robust blind watermarking method for volume data. Which address the problems of authentication and protection of personal information. The scheme obtains the feature vectors of volume data and quantizes them to generate the hash value of the volume data. By combining the concept of zero-watermarking, the algorithm for watermarking of volume data that is robust to geometric attacks. The experimental results demonstrate that the proposed algorithm has good invisibility and robustness

Keywords: watermarking, perceptual hashing, volume data, DFT

1 Introduction

With the progress of computer technology, the application of multimedia has a qualitative leap. But security concerns over copyright violation of multimedia data have also increased at the same time. On the one hand multimedia data can faster and more efficient transmitted in public network [1], on the other hand intercept and manipulation of the multimedia information has also become very easy [2]. Thus, the information security of multimedia data has attracted a lot of attention during the last few years.

Digital watermarking is an efficient tool for multimedia information protection [3]. However, the directions of research have been mostly in image [4], audio [5] and video watermarking [6]. Currently, there are a lot of volume data in real life. Such as most of the medical image (CT, MRI, etc.) is volume data, so study how to embed the digital watermarking in the volume data is significant. The volume data is not allowed to modify the content in principle [7]. As a result, to embed watermarking in volume data is difficult. Discrete cosine transform (DCT) [8], Discrete Fourier transform (DFT) [9] and discrete wavelet transform [10,11] are used in embedding watermarking of volume data. But the robustness of the algorithms is not very ideal. Wu [12] develop an algorithm based on the spread-spectrum communication technique to watermarking a volume data which is invisible and robust. However, the original volume data is needed in watermarking detection. It's not blind watermarking.

In allusion to invisible and robust Image Watermarking, there are a series of requirements. First, we hope the embedding of watermarking could not change the original image [13]. What is more, the watermarking must have good robustness and invisible. At last, we wish the capacity of watermarking is bigger. Whereas to the traditional digital watermarking algorithm, difficult to achieve all requirements at a time.

In this paper, we propose a watermarking algorithm based on perceptual hashing which is a blind multi-watermarking algorithm and also can achieve a true embedded zero-watermarking [14]. The experiment results demonstrate that the algorithm has good robustness.

2 Theoretical background

2.1 THE 3D DISCRETE FOURIER TRANSFORM

The discrete Fourier transform is an important mathematical tool on the engineering application. Assuming the size of volume data is $X \times Y \times Z$. The corresponding 3D-DFT is done using:

$$F(u,v,w) = \sum_{x=0}^{X-1}\sum_{y=0}^{Y-1}\sum_{p=0}^{Z-1} f(x,y,z)\cdot e^{-j2\pi xu/X} e^{-j2\pi yv/Y} e^{-j2\pi zw/Z}, \quad (1)$$

$$u = 0,1,...,X-1;\ v = 0,1,...,Y-1;\ w = 0,1,...,Z-1.$$

The corresponding volume data's inverse discrete Fourier transform (IDFT) is computed using:

$$f(x,y,z) = \frac{1}{XYZ}\sum_{u=0}^{X-1}\sum_{v=0}^{Y-1}\sum_{w=0}^{Z-1} F(u,v,w)\cdot e^{j2\pi xu/X} e^{j2\pi yv/Y} e^{j2\pi zw/Z}, \quad (2)$$

$$x = 0,1,...,X-1;\ y = 0,1,...,Y-1;\ z = 0,1,...,Z-1.$$

Note that in our case $f(x,y,z)$ is the value at the point (x,y,z) of the volume data, $F(u,v,w)$ is the three-dimension DFT coefficient at the point (u,v,w) in frequency domain. Volume data is composed of many layers of slices, each slice is a two-dimensional image. The size of image is $M \times N$, the number of slice's layers is P.

2.2 PERCEPTUAL HASHING

In 2001, Kalker first proposed the concept of perceptual hashing. A majority of existing algorithms follow a three-step framework to generate a hash value [15], as illustrated in Figure 1.

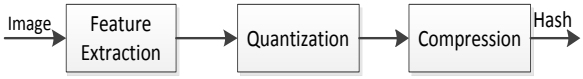

FIGURE 1 An example. Good quality with clear lettering

Perceptual hashing is a class of one way mappings from multimedia presentations to a perceptual hash value in terms of their perceptual content [16]. Perceptual hashing algorithm can transform volume data into binary sequences, and can be used to database search, content authentication, and watermarking [17-21]. The characteristics of the perceptual hashing function are robustness, collision resistance, compactness and one-wayness [16,22-25]. The specific method of perceptual hashing algorithm used in this paper was as follow:

Step 1: 3D-DFT to the volume data;

Step 2: 3D-IDFT to the precious 4×4×4 DFT coefficients;

Step 3: Calculate the average value of the real part of 4×4×4 IDFT coefficients.

Step 4 Compare the each IDFT real coefficient with the average. Greater than or equal to the average, recorded as 1. Less than the average, recorded as 0.

Step 5 Group the comparison result of the previous step together to constitute a 64 bits binary sequence, which is the hash value of the volume data. Group order is not important, as long as the order of all volume data using the same.

3 The watermarking algorithm

We choose a set of binary pseudo-random sequence Bg, Bg={bg(i)|bg(i)=0,1;1≤i≤L} represents information as multi-watermarking. Then, we select one MRI medical volume data as the original volume data which is describe as $F=\{f(i,j,k)|f(i,j,k)\in R;1\le i\le M,1\le j\le N,1\le k\le P\}$, where $w(j)$ and $f(i,j,k)$ represent the pixel gray-values of watermarking and the voxel values of the original volume data similar to the pixel gray-values of 2D image. To facilitate the operation, we assume $M1=M2=M$, $N1=N2=N$.

3.1 HASH VALUE EXTRACTION METHOD OF VOLUME DATA

Though the above method of perceptual hashing, we can extract the hash value of the volume data. That is to say: first, we use the 3D-DFT to the original medical volume data by the geometric transformation on each slice. We select the previous 4×4×4 coefficients. Then, the selected coefficient is computed using 3D-IDFT. We recognize the real part of IDFT coefficients as the feature vector of the volume data. Then, through the comparison of feature vector and the real part coefficients average realize binary quantization. At last, we can generate the hash value of volume data.

In order to prove that the robustness of the hash value, which we select above. We randomly choose 8 coefficients of the feature vector ($F(1,3,4)$, $F(1,4,1)$,…,$F(4,3,4)$, $F(4,4,1)$), which show in Table 1 We can see that the value of the corresponding coefficients have changed after the volume data has undergone an attack (which is show in Figures 2 and 3) as illustrated in column "L2-L9". But the hashing value unchanged, as shown in Table 1. It can be seen that the normalized cross-correlation (NC) between the hashing values is equal to 1.0, as shown in column "L12". Therefore, the hash value can meet the perceptual robustness.

Collision resistance is one of the important properties of perceptual hash value. Collision resistance means that there is large difference the hash value of two no similar images. In order to further illustrate the perception of the hash value, we select some different volume data as test objects which are shown in Figure 4. Calculate the NC between hash values of different test objects, as illustrated in Table 2.

In Table 2, we can see that the NC is largest between volume data itself, which is 1.00. The NC of a and b is larger, because a and b are brain volume data. The other NC values are small, which are all less than 0.5. That is observed with our human eyes. Therefore, collision resistance of the hash value in our algorithm is good.

TABLE 2 The NC between test volume data

NC	a	b	c	d	e

FIGURE 4 Different volume data which are test objects

3.2 EMBEDDING WATERMARKING

Step 1: Acquire the hash value of the original volume data. In his section, we use the proposed perceptual hashing algorithm to the original volume data. Through volume data's feature extraction and binary quantization process, and then, we can get the hash value of the original volume data:

$$FF_4(i,j,k)=DFT3(F(i,j,k)), \tag{3}$$

$$FIF(i,j,k)=IDFT3(FF_4(i,j,k)), \tag{4}$$

$$RIF(i,j,k)=REAL(FIF(i,j,k)), \tag{5}$$

$$H(j)=BINARY(RIF(i,j,k)). \tag{6}$$

Step 2: Utilizing the HASH function of cryptograph, the logical sequence can got by us, $Key^g(j)$:

$$Key^g(j)=H(j)\oplus B^g(j), \tag{7}$$

where $H(j)$ is the hash value of volume data, B^g is the multi-watermark sequence. $Key^g(j)$ is a binary sequence. The $Key^g(j)$ is necessary to extract the watermarking, it would be saved. Moreover, we can take the $Key^g(j)$ for a secret key. In order to protect the copyright of the original volume data, we should registered the $Key^g(j)$ at the third part. In addition, during the watermarking embedding, the original volume data change a little. It's one of the zero-watermarking technologies.

3.3 EXTRACT WATERMARKING

Step 3: Acquire the hash value of the tested volume data. The perceptual hashing method is also performed on the test volume data $F'(x,y,z)$. As the same as Step 1, we can acquiring the hash value $H'(j)$.

$$FF'_4(i,j,k)=DFT3(F'(i,j,k)), \tag{8}$$

$$FIF'(i,j,k)=IDFT3(FF'_4(i,j,k)), \tag{9}$$

$$RIF'(i,j,k)=REAL(FIF'(i,j,k)), \tag{10}$$

$$H'(j) = BINARY\left(RIF'(i,j,k)\right), \quad (11)$$

Step 4: Utilizing the binary sequence $Key^g(j)$ and the hash value of tested volume data $H'(j)$, we can extract the watermarking $B^g'(j)$:

$$B^g'(j) = H'(j) \oplus Key^g(j), \quad (12)$$

$B^g'(j)$ describe the extracted multi-watermarking, can be also computed by the HASH function of cryptography. $Key^g(j)$ are obtained from Step 2.

3.4 WATERMARKING EVALUATING ALGORITHM

By calculating NC to determine whether it is embedded watermarking or not. We use NC to measuring the quantitative similarity between the extracted and embedded watermarking. The higher the value of NC is, the more approximation between the extracted watermarking $B^g(j)$ and the embedded watermarking $B^g'(j)$. Defined as:

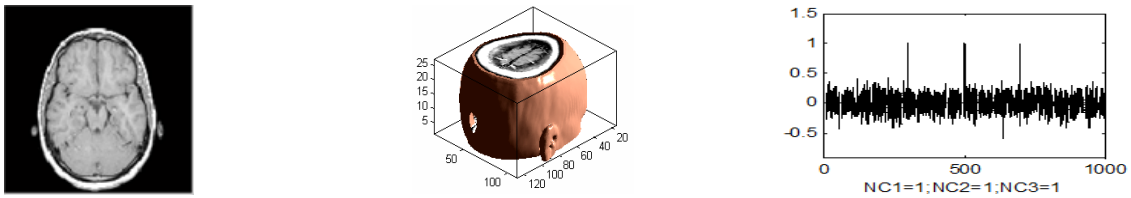
$$NC = \frac{\sum_j B^g(j) B^g'(j)}{\sum_j B^g(j) B^g(j)}. \quad (13)$$

4 Experiment results on robustness of the watermarking algorithm

We have implemented the volume data watermarking algorithm in Matlab2010a platform to verify the effectiveness. In these experiments, we should do these with the help of a thousand groups of independent binary pseudo-random sequences as used. Every sequence consists of 64 bits. In the experiment, the 300th, the 500th and the 700th group are selected at random from the thousand groups as the embedded watermarking. The size of the volume data (MRI.mat) is 128×128×27, which is offered in matlab.

It can be seen visually from Figure 5 that the quality of the volume data embedded has hardly any change. The quality of extracted watermarking is of high-quality with no difference with the original in normal case, all the NC are 1.0, which is shown in Figure 5a. (no attacking on watermarking)

The following are several types of common and geometric attacks to test the robustness of the algorithm. By attacks on each slice to achieve the purpose that an attack on the volume data in this experiment.



a) b) c)

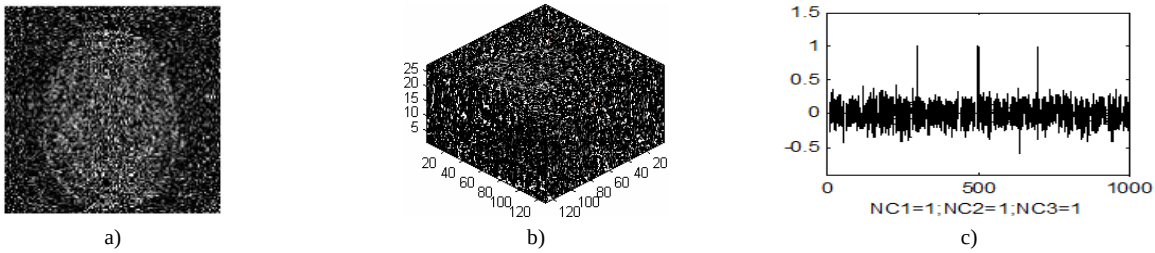
FIGURE 5 No attacking on watermarking: a) a slice of original volume data; b) the original volume data; c) watermarking detector

4.1 COMMON ATTACKS

In general, common attacks are common image processing. For example: Gaussian noise, digital to analogue and analogue to digital conversion, quantization and requantization, JPEG, median filtering and so on.

4.1.1 Gaussian noise

Figures 6a and 6b show the slice and volume data with the Gaussian noise (10%), respectively. As the Figure 6c shows, the PSNR is 3.30dB, and the multi-watermarking sequence can be detected, all of the NC are 1.00. Different parameters of noise impact on the volume data. The corresponding different PSNR and NC are given in Table 3. The result shows the value of NC is when the noise parameter top to 25%. Therefore, our algorithm has strong robustness against noise attacks.



a) b) c)

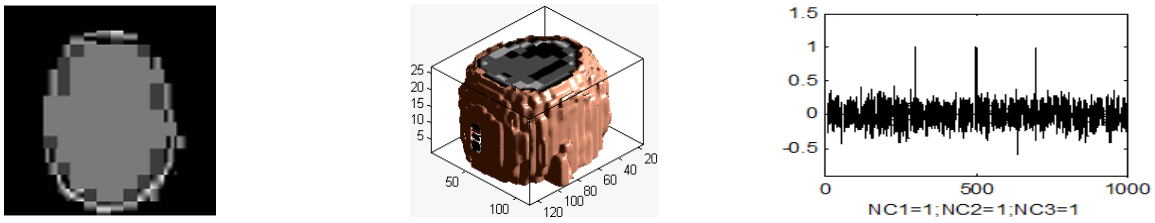
FIGURE 6 With noise attack: a) a slice with noise attack; b) the corresponding volume data; c) watermarking detector

TABLE 3 The PSNR and corresponding NC with Gaussian noise

Noise parameters (%)	1	3	5	10	15	20	25
PSNR	12.52	8.02	6.03	3.32	1.80	0.82	0.10
NC1	1.00	1.00	1.00	1.00	1.00	1.00	1.00
NC2	1.00	1.00	1.00	1.00	1.00	1.00	1.00
NC3	1.00	1.00	1.00	1.00	1.00	1.00	1.00

4.1.2 JPEG attacks

Figure 7a indicates the slice with JPEG attack (5%). Figure 7b indicates the corresponding volume data. As the Figure 7c displays the multi-watermarking sequence can be detected, NC1=1.00, NC2=1.00, NC3=1.00. Table 4 gives the PSNR and corresponding NC when different parameters of JPEG attacks are inflicted on the volume data. If the compression quality is down to 2%, the multi-watermarking still can be detected nevertheless. When the JPEG attacks, the results demonstrate that algorithm is robust.



a) b) c)

FIGURE 7 With JPEG attack (10%): a) a slice with JPEG attack; b) the corresponding volume data; c) watermarking detector

TABLE 4 The PSNR and corresponding NC with JPEG attacks

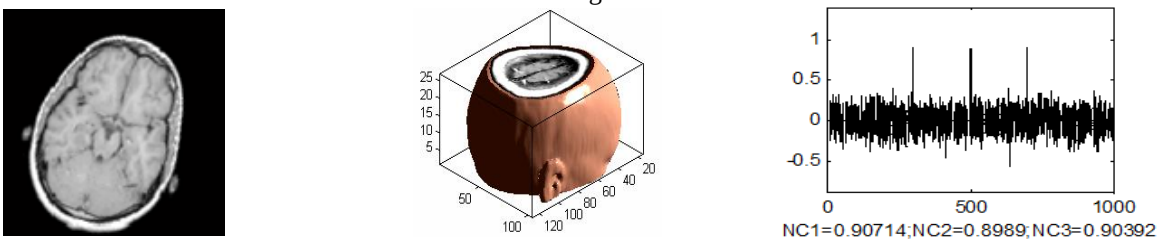
Compression quality (%)	2	4	8	10	20	40	60
PSNR	16.57	17.82	20.21	21.20	23.10	25.06	26.61
NC1	1.00	1.00	1.00	1.00	1.00	1.00	1.00
NC2	1.00	1.00	1.00	1.00	1.00	1.00	1.00
NC3	1.00	1.00	1.00	1.00	1.00	1.00	1.00

4.2 GEOMETRIC ATTACKS

Geometric attacks are refer to the watermarking image under rotation, scaling, cropping, translation and so on. It is almost the watermarking attack method which is hardest to solve. The implementation of the geometric attacks is very convenient. Just simple geometric attacks are often can cause the loss of watermarking. It affects the effectiveness of the watermarking algorithm greatly. Resistance to geometric attacks is a focus in the study of watermarking algorithm.

4.2.1 Rotation attacks

The slice with 20° rotated clockwise is indicated in Figure 8a. The corresponding volume data is indicated in Figure 8b. As the Figure 8c) displays the multi-watermarking sequence can be detected, NC1=0.91, NC2=0.90, NC3=0.90. Table 5 givers the PSNR and corresponding NC when different rotated angles are inflicted on the volume data. As the angle of rotation top to 35°clockwise, the multi-watermarking can be detected, too. When the rotation attacks, the results demonstrate that algorithm is robust.



a) b) c)

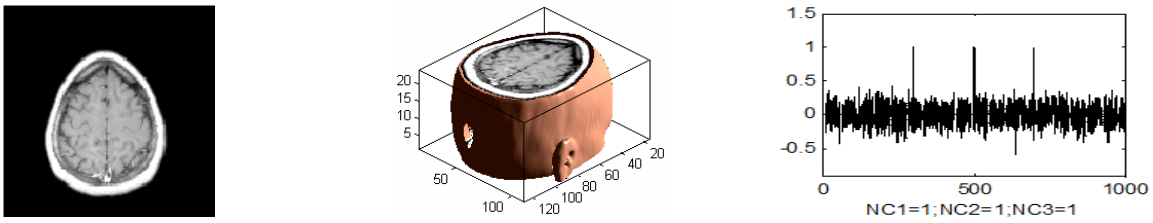
FIGURE 8 With rotation attack (20°): a) a slice with rotation attack; b) the corresponding volume data; c) watermarking detector

TABLE 5 The PSNR and corresponding NC with rotation attacks

Rotated (clockwise)	5	10	15	20	25	30	35
PSNR	16.54	13.97	12.98	12.44	12.04	11.68	11.33
NC1	0.97	0.94	0.91	0.91	0.88	0.84	0.84
NC2	0.96	0.93	0.90	0.90	0.87	0.83	0.83
NC3	0.97	0.94	0.90	0.90	0.87	0.85	0.85

4.2.2 Cropping attacks

The slice under cropping 10% from *Z* displays on Figure 9a. Then, the corresponding volume data is shown in Figure 9b. Figure 9c shows that the watermarking can be detected, NC1=1.00, NC2=1.00, NC3=1.00. Different cropping rates inflict on the volume data, the corresponding NC are given in Table 6. Hence, we can conclude the algorithm is robust to cropping attacks.



a) b) c)

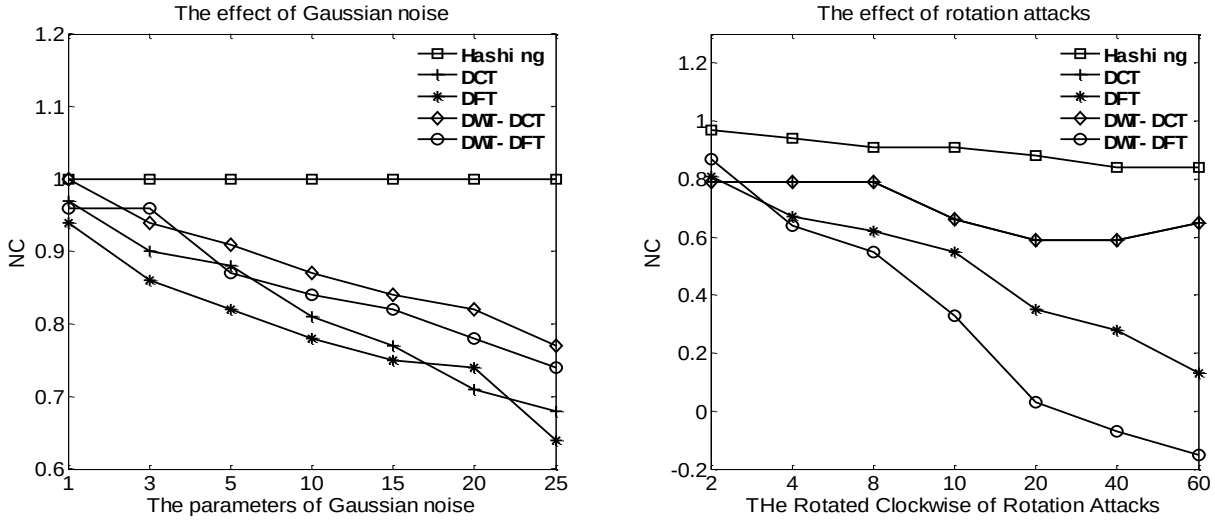
FIGURE 9 With noise attack: a) a slice with noise attack; b) the corresponding volume data; c) watermarking detector

TABLE 6 The PSNR and corresponding NC with cropping attacks

Cropping rate (from Z %)	**2**	**4**	**6**	**8**	**10**	**20**	**40**
NC1	1.00	1.00	1.00	1.00	1.00	0.97	0.88
NC2	1.00	1.00	1.00	1.00	1.00	0.97	0.87
NC3	1.00	1.00	1.00	1.00	1.00	0.97	0.88

4.3 ALGORITHM COMPARISON

In order to further demonstrate the robustness properties, we consider the performance of others volume data watermarking schemes, such as DCT, DFT, DWT-DCT, DWT-DFT [8], [10-11], [26]. We show the comparison results with different attacks in terms of NC in Figure 10. The results account for that the proposed volume data watermarking algorithm has good robustness. The performance for Gaussian noise and rotation attacks, are shown in Figure 10. In the case of Gaussian noise, the NC of the proposed perceptual hashing algorithm all are1.00. We can also observe that the NC of other volume data watermarking schemes are less than 1.00. We show the performance for rotation attacks is shown in Figure 10. In the case of rotation attacks, the NC of the perceptual hashing algorithms is very high. The NC of DCT scheme and DWT-DCT scheme are the same. In all, we observe that the proposed volume data watermarking scheme perform very well for both common attacks and geometric attacks. The algorithm has good robustness against common attacks and geometric attacks



a) b)

FIGURE 10 The performance of watermarking schemes under common attacks. a) Gaussian noise; b) JPEG attacks. To generate a point on the curve, X-axis is the volume data under different attacks; the corresponding watermarking of resulting volume data was detected. And the corresponding NC with the original watermarking is shown in the Y-axis.

5 Conclusion

A novel blind watermarking scheme appropriate for 3D volume data by using perceptual hashing was proposed in this paper. The method combines DFT transform, feature vector and database technology. The watermarking is a blind watermarking. In addition, the embedding of watermarking would not change the volume data. And the multi-watermarking could be embedded in volume data. It proved that the algorithm has a great capacity of watermarking embedding. The experiments results show that the algorithm has good robustness against common and geometric attacks, In a word, it is a efficiency algorithm.

Abstract

With the popularization of Internet and the development at full speed of the multi-media technology, the copyright protection of digital works has already become the hot issue at present. Generally speaking, image, audio and video watermarking is comparatively similar in algorithm realization, with their redundancy, in which we can embed watermark. But other than the aforementioned, there is no redundancy to transfer secret info in text document. Nowadays, to embed watermark in text documents are limited to methods such as shifting the line and word, amending the characters' traits and disposing in the level of semantics. All these algorithms are not robust or lack of concealment, generally not serving the turn of Chinese text documents riffles. Based on the studies of the document digital watermarking methods and techniques, this dissertation presents that the problems of existed documents watermarking algorithms can be solved by Arnold Scrambling and DFT technique. The experimental results show that the scheme has strong robustness against common attacks and geometric attacks.

Keywords: Arnold scrambling, digital watermarking, DFT, zero-watermarking, text image

1 Introduction

With the rapid development of computer science and technology, and multimedia communication technology, digital media is becoming more and more universal. Digital watermarking is an important method for protecting digital media copyright. Most work focuses on audio, video, grayscale, and color images. However, binary images are very useful for security records, insurance information, financial document, fax images, case history, contract, e-business, e-Government, etc. Therefore, it may be very useful to embed and extract watermarking in binary images. For binary images, pixels take only two different values. Hence, embedding watermarking without causing visible perceivable changes in binary images is more difficult than in grayscale images. Brassial et al. proposed to change line spacing to embed the watermarking. Huang et al. presented a way to change word spacing to embed the watermarking. By changing a particular feature of an individual character can be embed with the watermarking. However there are some disadvantages to these watermarking approaches. The amount of data that can be hidden is few. The Process of embedding and extracting the watermarking is very complicated. Furthermore, these algorithms are vulnerable to many attacks, especially to geometric attacks.

This paper proposes an algorithm which combines DFT and Arnold scrambling. The algorithm combines both the first generation watermarking techniques and the second generation watermarking techniques. In the watermarking embedding process, firstly, the watermarking is encrypted by scrambling transformation technology, then the encrypted watermark information is embedded in the text of DFT transform image, to obtain a feature vector of the text image, then use the eigenvectors and watermarking information by HASH function to generate a binary logic series, as the sequence of keys. The result of experiment indicates that the algorithm can achieve a true embedded zero-watermarking. Meanwhile, it has a strong robustness against common attack and geometric attack.

2 The fundamental theory

2.1 ARNOLD SCRAMBLING TRANSFORM (AT)

Scrambling transformation as a means of encrypted technology is applied in the pretreatment stage of the watermarking, after scrambling transformation, one meaningful watermarking will become a meaningless, chaotic image. If you do not know the scrambling algorithm and keys, the attacker can not recover it even if he gets the watermarking from the embedded watermarking. And thus plays a role of secondary encryption. Additionally, after scrambling transformation, it will upset the relationship between the space locations of pixels and make it evenly distributed in all space of the carrier image. This will improve the robustness of the algorithm. Two-dimensional Arnold scrambling transformation is defined as follows:

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{bmatrix} 1 & 1 \\ 1 & 2 \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} \bmod N; x, y = \{0,1,2...,N-1\}, \quad (1)$$

where x, y is the pixel coordinates of the original space: x', y' is the pixel coordinates after iterative computation scrambling, N is the size of the rectangular image, also referred to as a step number.

By the above formula, the corresponding inverse

* ***Corresponding author*** e-mail: Jingbingli2008@hotmail.com

transform formula can be obtained:

$$\begin{bmatrix} x \\ y \end{bmatrix} = \left(\begin{bmatrix} 2 & -1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} x' \\ y' \end{bmatrix} + \begin{bmatrix} N \\ N \end{bmatrix} \right) \bmod N, \quad (2)$$

$$x', y' = \{0,1,2...,N-1\}.$$

It is easy to restore the original initial state according to the corresponding iterations. Arnold transformation is cyclical, when iterate to a step, will regain original image. So if you do not know cycle and iterations, you will not be able to restore the image. Therefore, cycle and iterations can exist as a private key. Meanwhile, different image, because the desired effect is different, iterations should also be changed according to your need.

2.2 A METHOD TO OBTAIN THE FEATURE VECTOR OF TEXT IMAGE

First, the original image is computed using DFT. Then, we choose 5 low-frequency coefficients ($F(1,1)$, $F(1,2)$, …, $F(1,5)$) for formation of the feature vector, shown in Table 1. We find that the value of the low-frequent coefficients may change after the image has undergone an attack, particularly geometric attacks. However, the signs of the coefficients remain unchanged even with strong geometric attacks, as also shown in Table 1. Let "1" represents a positive or zero coefficient, and "0" represents a negative coefficient, and then we can obtain the sign sequence of low-frequency coefficients, as shown in the column "Sequence of coefficient signs" in Table 1. After attacks, the sign sequence is unchanged, and the Normalized Cross-correlation (NC) is equal to 1.0.

This means that the signs of the sequence can be regarded as the feature vector of the text image. Furthermore, it proves that the sequence of the DFT coefficient signs can reflect the main visual characteristics of text images.

TABLE 1 Change of DFT low-frequency coefficients with respect to different attacks

Image processing	PSNR	F(1,1)	F(1,2)	F(1,3)	F(1,4)	F(1,5)	Sequence of coefficient signs	NC

3 Robust watermarking algorithm based on digital text image

Use a meaningful binary image as the watermarking, Represented by W, F represents the original text image. $W=\{w(i, j)|w(i, j) = 0,1;\ 1\le i\le M1,\ 1\le j\le M2\}$ as digital watermarking, At the same time, we select a paragraph in an article as the original text image. It is describe as: $F = \{f(i, j)|f(i, j)\in R;\ 1\le i\le N1,\ 1\le j\le N2\}$, where $w(i, j)$ and $f(i, j)$ denote the pixel gray values of the watermarking and the original text image. Let $M1 = M2 = M$, $N1 = N2 = N$.

3.1 THE ALGORITHM OF THE EMBEDDED WATERMARKING

Step 1 Acquire the the encrypted watermarking image. The binary watermarking image is scrambled by Arnold scrambling transform, $BW(i, j)$.

$$BW(i, j) = AT(W(i, j)). \quad (3)$$

Step 2 Acquire the feature vector of the original text image. First, DFT of the whole $F(i, j)$ is computed as the DFT coefficient matrix, $FF(i, j)$. Then, after arranging the DFT coefficients from low to high frequency, the low-frequency sequence $Y(j)$ can be obtained. Finally, the feature vector $V=\{v(j)|v(j) = 0 \text{ or } 1;\ 1 \le j \le L\}$, can be achieved as a signs sequence of the top L values in the low-frequency $Y(j)$ by symbolic computation. Where the value of L can tune the robustness and capability of the embedded watermarking (in this paper we set $L = 32 = 4 \times 8$ bits).

$$FF(i, j) = DFT2(F(i, j)), \quad (4)$$

$$V(j) = -Sign(Y(j)). \quad (5)$$

Step 3 Generate the public key sequence. Utilizing the encrypted watermarking BW(i, j) and the feature vector V(j), we can generate the public key sequence, Key(i, j).

$$Key(i, j) = V(j) \oplus BW(i, j). \quad (6)$$

The public key sequence, $Key(i, j)$, can be computed by the HASH function of cryptography. The $Key(i, j)$ should be stored for extracting the embedded watermarking later. Furthermore, $Key(i, j)$ can also be regarded as a public key and registered to the third part to preserve the ownership of the original image registered to the third part to preserve the ownership of the original text image, so as to achieve the purpose of the protection of text images.

3.2 THE ALGORITHM OF THE EXTRACTED WATERMARKING

Step 1 Acquire the feature vector of the tested image. This process of acquiring the feature vector $T\_V'(j)$ is same tostep1 of the watermarking embedding process. The obtained feature vector, $T\_V'(j) = \{t\_v(j)|t\_v(j) = 0 \text{ or } 1; 1 \le j \le L\}$, also consists of the signs sequence of the DFT coefficients, where L has the same meaning as previously.

$$FF'(i,j) = DFT2(F'(i,j)), \tag{7}$$

$$T\_V'(j) = -Sign(Y'(j)). \tag{8}$$

Step 2 Extracting the watermarking BW'(i, j). According to the key, which generated in the embedded watermarking and the visual feature vector $T\_V'(j)$ of the being tested image, use HASH function properties to extract the watermarking $BW'(i, j)$. Extracting watermarking doesn't need original image, so it can protect the original image better.

$$BW'(i,j) = Key(i,j) \oplus T\_V'(j), \tag{9}$$

Step 3 Using the Arnold scrambling inverse transform to restore the extracted watermarking $BW'(i, j)$, get the watermarking of the being tested image, $W'(i, j)$.

$$W'(i,j) = IAT(BW'(i,j)). \tag{10}$$

3.3 DETECTION ALGORITHM OF THE WATERMARKING

Step 1 By calculating *NC* (Normalized Cross-Correlation) to determine whether there is the existence of the watermarking. The larger the value of *NC* is, the more approximation between $W'(i, j)$ and $W(i, j)$. Defined as:

$$NC = \frac{\sum_i \sum_j W(i,j) W'(i,j)}{\sum_i \sum_j W^2(i,j)}, \tag{11}$$

where $W(i, j)$ is the original watermarking, $W'(i, j)$ is the extracted watermarking.

Step 2 Evaluation of the quality of the text image after Embed watermarking by calculating the peak signal-to-noise ratio PSNR (dB), we often use peak value signal-to-noise ratio PSNR (dB) to reflect the quality of signal, defined as:

$$PSNR = 10 \lg \frac{MN \max_{i,j} (I(i,j))^2}{\sum_i \sum_j (I(i,j) - I'(i,j))^2}, \tag{12}$$

where $I(i, j)$, $I'(i, j)$ denote the pixel gray values of the coordinates (i, j) in the original image and the watermarking, respectively. M, N represent the image row and column numbers of pixels, respectively.

4 Experiments

To verify the effectiveness of our proposed algorithm, we carried out the simulation in Matlab2010a platform. We choose a significant binary image as the original watermarking and select a paragraph in an article as the original text image. The original watermarking $W = \{w(i, j)|w(i, j) = 0 \text{ or } 1; 1 \le i \le 32, 1 \le j \le 32\}$. The original text image $F = \{f(i, j), 1 \le i \le 128, 1 \le j \le 128\}$.

In the experiment, the parameter values: Arnold scrambling period is 24, and the number of transform times are 10, i.e. T=24, n=10.

Figure 1 represents the results when a binary watermarking is scrambled by Arnold scrambling transform. Figure 1a is the original watermarking. Figure 1b is the scrambled watermarking when n equaled to eight. Figure 1c shows the restored watermarking.

a) b) c)

FIGURE 1 The watermarking is scrambled by Arnold scrambling transform: a) the original watermarking, b) the scrambled watermarking, c) the restored watermarking

In order to investigate this approach of embedding watermarking robust performance, the verification described below is chosen.

4.1 COMMON ATTACKS

4.1.1 Adding Gaussian noise.

In the watermarked text image, Gaussian noise is added by the noise function with different noise level. The text image under the attack of Gaussian noise (10%) with PSNR=12.96dB. At this time, the watermarked text image has been very vague, as shown in Figure 2a. The watermarking can obviously be extracted with NC=1.0. As shown in Figure 2b. The results prove that our proposed algorithm has strong robustness against noise attacks.

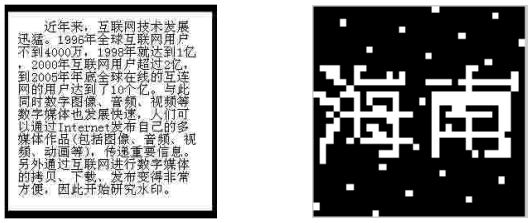
FIGURE 2 The watermarked text image under Gaussian noise attacks (10%): a) the watermarked text image under noise attack, b) the extracted watermarking

4.1.2 JPEG attacks

JPEG compression process is done by using the percentage of image quality as a parameter to measure. The

watermarked text image with *PSNR* = 17.71dB under JPEG attacks (10%) is shown in Figure 3a. the watermarking can obviously be extracted with *NC* = 0.93 as shown in Figure 3b. The results show that the watermarking algorithm has strong robustness against JPEG attacks.



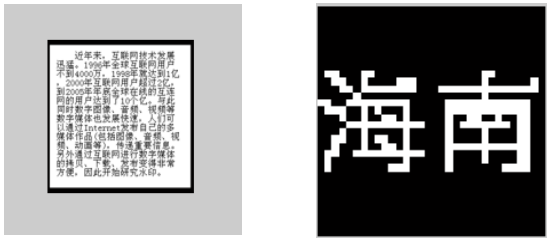
a) b)

FIGURE 3 The watermarked text image under JPEG attacks (10%): a) the watermarked text image under JPEG attacks, b) the extracted watermarking

4.2. GEOMETRICAL ATTACKS

4.2.1 Scaling attacks

We use the scaling factor as parameter to validate the effectiveness of our proposed algorithm on different scaling attacks. When the watermarked image is scaled 0.5 times, its pixel point has become the double of the original. Figure 4a shows that the watermarked image shrunk with a scale factor of 0.5. Moreover, Figure 4b shows that the watermarking can be extracted with *NC* = 1.00. It proves that our proposed algorithm has strong robustness against scaling attacks.

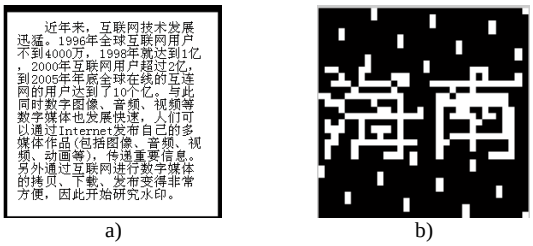


a) b)

FIGURE 4 The watermarked text image under scaling attacks: (0.5 times), a) the watermarked text image under scaling attacks, b) the extracted watermarking

4.2.2 Cropping attacks

The cropping attacks are added to the watermarked image for validating the effectiveness of our proposed algorithm. Figure 5a shows that the medical image cropping from *Y* axis with the ratio of 2%. Moreover, Figure 5b shows that the watermarking image can be extracted with *NC* = 0.87. The results show that the watermarking algorithm has strong robustness against cropping attacks.



a) b)

FIGURE 5 Under cropping attacks (from the *Y* axis, 2%): a) an image with cropping attack, b) the extracted watermarking image

5 Conclusion

This paper presents a watermarking encryption algorithm based on Arnold scrambling and DFT for text images, combing the visual feature vector of image, the encryption technology and the concept of third-party, and integrating Arnold scrambling. In watermarking embedding process, Arnold scrambling is employed to preprocess on the original watermarking. Without knowing the scrambling algorithm and key, the attackers cannot recover the images even after extracting the watermarking from the watermarked image. Such additional encryption provides double protection for text images. Our experiments show the proposed embedding watermarking scheme has robustness for common attacks and geometrical attacks while still keeping the quality of the original text image. Moreover, the proposed watermarking algorithm can be applied to protecting the other area's images.

Abstract

In order to analysis and predict data, a new intelligent algorithm (opposite degree algorithm) is used for actual engineering example. The algorithm is based on concept of prior numerical, posterior values and opposite degree in the nature. The human's languages have positive words and negative words. The matrix method can calculate the opposite degree and predict data by considering data's relationship and opposite degree. At the same time, relevant results are obtained through the opposite degree calculation by using the data of coal and gas outburst. After the comparison of the actual results, the accuracy of prediction is 100%. The preliminary validation of opposite degree algorithm shows that the algorithm is basically feasible and effective. If this algorithm can be improved, it is expected to be applied in practical fields more widely.

Keywords: opposite degree, algorithm, engineering data processing, coal and gas outburst, prior value, posterior value, prediction method

1 Introduction

In China, coal and gas outburst accidents often happen in the disasters. Every year, a number of incidents caused casualties. Therefore, it has a very important realistic significance for the study of coal and gas prediction. There are lots of staff's deaths or injury event in China. So it has an important practical significance to research the forecasting methods in the field of mining engineering. In the study of engineering, there are many intelligent algorithms has been used. There are lots of new intelligent algorithms and improved algorithms for solving engineering problems, such as data driven nonlinear control strategy [1], improved GA-ANFIS [2], improved SVM [3] and CIP [4] and HCDCCMM [5] and so on. This research tries to put forward a new method for computing the opposite degree, and hope to be able to predict the classification. In order to verify the effectiveness of the algorithm, based on the coal and gas outburst instance data, we make a prediction results compared with other method. In the nature, the opposite degree is inseparable from the use of the synonyms, and antipodal opposites in people's daily life [6-8]. Judging from intuition, the opposite degree between "male" and "female" is relatively absolute, and the opposite degree should be very high. So, for intelligent information processing, especially in nature situation, it is very important to use a precise method to represent the relationship between the real relationships.

2 Opposite degree algorithm

Opposite degree is proposed by Xiao-Guang Yue [9], and it has many species can be divided into two or more than two kinds, called gender. Typically, a species can have two kinds of gender: male and female. Therefore, creatures with the opposition can be applied in the analysis of opposition a group of engineering data.

The definition of opposite degree are presented, mainly involves the following aspects:

1) A priori value refers to the value for the training.

2) A posteriori numerical refers to numerical prediction analysis.

3) Opposite degree is a priori and posteriori numerical value between degrees of difference, $(-\infty, +\infty)$ is the range of the values.

In general, the definition of opposite degree is C, a priori value is A, the posterior value is B:

$$C = \frac{B-A}{A} = \begin{cases} < 0, B < A \\ = 0, A = B \\ > 0, B > A \end{cases},$$

[*]***Corresponding author*** e-mail: xgyue@whut.edu.cn

C is close to +∞, it shows that *B* is more big, and indicates that the difference of *B* and *A* is greater. *C* is close to –∞, it shows that *B* is small, and indicates that the difference of *B* and *A* is greater. *C* is close to 0, indicating that *B* and *A* are closer. *C* is equal to 0, show that the *A* is equal to *B*.

There is a prior matrix $A_{m\times n}$:

$$A_{m\times n}=\begin{bmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ \dots & \dots & \dots & \dots \\ a_{m1} & a_{m2} & \dots & a_{mn} \end{bmatrix}.$$

The classification column vector of $A_{m\times n}$ is *X*:

$$X=\begin{bmatrix} x_1 \\ x_2 \\ \dots \\ x_n \end{bmatrix}.$$

There is a posterior matrix $B_{p\times n}$:

$$B_{p\times n}=\begin{bmatrix} b_{11} & b_{12} & \dots & b_{1n} \\ b_{21} & b_{22} & \dots & b_{2n} \\ \dots & \dots & \dots & \dots \\ b_{p1} & b_{p2} & \dots & b_{pn} \end{bmatrix}.$$

The opposite degree of $A_{m\times n}$ and $B_{p\times n}$ can be calculated by using the following equation:

$$C(a_{ij},b_{kj})=\frac{b_{kj}-a_{ij}}{a_{ij}}.$$

Based on the opposite degree calculation, the corresponding classification column vector *Y* of $B_{p\times n}$ can be calculated:

$$Y=\begin{bmatrix} y_1 \\ y_2 \\ \dots \\ y_p \end{bmatrix}.$$

3 Calculation steps

1) According to the following formula, calculated separately for each line of the opposite, and returns the absolute value of the minimum value. $S(k)$ is the opposite degree calculation results of the *k* line data of $B_{p\times n}$ and each line of $A_{m\times n}$, the minimum absolute value can be got (if the results obtained with two or more than two of the same value, it returns the first value):

$$C(k)=\min\begin{cases} |\sum_{j=1}^{n}\frac{b_{kj}-a_{1j}}{a_{1j}}| \\ \dots \\ |\sum_{j=1}^{n}\frac{b_{kj}-a_{ij}}{a_{ij}}| \end{cases}.$$

2) Returns the corresponding x_i to the y_p, the *k* line classification of $B_{p\times n}$ can be obtained.

3) Repeat (1) and (2), until calculate all the results.

4) Output *Y*.

4 Analysis of calculation results

Firstly, the example of coal and gas outburst data comes from Yunnan Enhong coal mine [10]. This is a big coal mine in China. And 20 sets of data are selected as the training samples in Table 1. In order to do a comparison, 8 sets of data are selected as testing samples in Table 2. Initial speed, consistency coefficient, gas pressure, destruction of coal type and mining depth are selected as influencing factors in Table 2. We choose the factors. We choose the 5 factors based on effectiveness, independence and feasibility. The last column corresponds to the classification column vector.

Secondly, by using the OD algorithm, the opposite result is obtained (results accurate to four digits after the decimal point). Opposite degree calculation is based on each test data and 20 sets of training data; the results are shown in Table 3. In order to express the degree of deviation between the data, the data do not take absolute value. Where, the minimum data results indicate that is the minimum absolute opposite degree results, namely the forecast error data and the training data with minimum computational results.

Thirdly, the minimum opposite degree results and corresponding approximate data rows are shown in Table 4.

Finally, the experimental results show that the accuracy of OD algorithm is 100% (as shown in Table 5). The accuracy of OD and accuracy of Chen Zuyun et al's method [10] are the same (as shown in Table 6). This results show that the algorithm has a positive role in classification and prediction.

5 Conclusions

Human thinking with divergent characteristics, new things in the human brain will produce antagonism and association. We propose a new intelligent algorithm – opposite degree algorithm. The algorithm can calculate the opposite degree of values, so as to achieve the purpose of classification and prediction. Meanwhile, in order to verify the effectiveness of the algorithm, using coal and gas outburst instance data and OD algorithms to predict the classification, and do a comparison with other methods. Its prediction result is 100%. The study shows that the algorithm is feasible and effective. The next focus of the work is divided into two parts, on the one hand, to further verify the algorithm from the point of view of mathematics, and attempts to prove that the algorithm is applicable and feasible; on the other hand, to further improve the algorithm, especially in the numerical prediction to make supplement, expected application in actual field more.
